## 1 Parsing and Specifying Syntax

The syntax/parse library provides a framework for writing macros and processing syntax. The library provides a powerful language of syntax patterns, used by the pattern-matching form syntax-parse and the specification form define-syntax-class. Macros that use syntax-parse automatically generate error messages based on descriptions and messages embedded in the macro's syntax patterns.

```
(require syntax/parse) package: base
```

### 1.1 Introduction

This section provides an introduction to writing robust macros with syntax-parse and syntax classes.

As a running example we use the following task: write a macro named mylet that has the same syntax and behavior as Racket's let form. The macro should produce good error messages when used incorrectly.

Here is the specification of mylet's syntax:

```
|(mylet ([var-id rhs-expr] ...) body ...+)
(mylet loop-id ([var-id rhs-expr] ...) body ...+)
```

For simplicity, we handle only the first case for now. We return to the second case later in the introduction.

The macro can be implemented very simply using define-syntax-rule:

```
> (define-syntax-rule (mylet ([var rhs] ...) body ...)
    ((lambda (var ...) body ...) rhs ...))
```

When used correctly, the macro works, but it behaves very badly in the presence of errors. In some cases, the macro merely fails with an uninformative error message; in others, it blithely accepts illegal syntax and passes it along to lambda, with strange consequences:

```
> (mylet ([a 1] [b 2]) (+ a b))
3
> (mylet (b 2) (sub1 b))
mylet: use does not match pattern: (mylet ((var rhs) ...)
body ...) at: (mylet (b 2) (subl b))
> (mylet ([1 a]) (add1 a))
lambda: not an identifier, identifier with default, or
```

```
keyword at: 1
> (mylet ([#:x 1] [y 2]) (* x y))
eval:2:0: arity mismatch;
    the expected number of arguments does not match the given
number
    expected: 0 plus an argument with keyword #:x
    given: 2
    arguments....
        l
        2
```

These examples of illegal syntax are not to suggest that a typical programmer would make such mistakes attempting to use mylet. At least, not often, not after an initial learning curve. But macros are also used by inexpert programmers and as targets of other macros (or code generators), and many macros are far more complex than mylet. Macros must validate their syntax and report appropriate errors. Furthermore, the macro writer benefits from the machine-checked specification of syntax in the form of more readable, maintainable code.

We can improve the error behavior of the macro by using syntax-parse. First, we import syntax-parse into the transformer environment, since we will use it to implement a macro transformer.

```
> (require (for-syntax syntax/parse))
```

The following is the syntax specification above transliterated into a syntax-parse macro definition. It behaves no better than the version using define-syntax-rule above.

```
> (define-syntax (mylet stx)
    (syntax-parse stx
        [(_ ([var-id rhs-expr] ...) body ...+)
            #'((lambda (var-id ...) body ...) rhs-expr ...)]))
```

One minor difference is the use of . . . + in the pattern; ... means match zero or more repetitions of the preceding pattern; . . .+ means match one or more. Only . . . may be used in the template, however.

The first step toward validation and high-quality error reporting is annotating each of the macro's pattern variables with the syntax class that describes its acceptable syntax. In mylet, each variable must be an identifier (id for short) and each right-hand side must be an expr (expression). An annotated pattern variable is written by concatenating the pattern variable name, a colon character, and the syntax class name.

```
> (define-syntax (mylet stx)
    (syntax-parse stx
        [(_ ((var:id rhs:expr) ...) body ...+)
            #'((lambda (var ...) body ...) rhs ...)]))
```

For an alternative to the "colon" syntax, see the $\sim$ var pattern form.

Note that the syntax class annotations do not appear in the template (i.e., var, not var:id).
The syntax class annotations are checked when we use the macro.

```
> (mylet ([a 1] [b 2]) (+ a b))
3
> (mylet (["a" 1]) (add1 a))
mylet: expected identifier at: "a"
```

The expr syntax class does not actually check that the term it matches is a valid expressionthat would require calling that macro expander. Instead, expr just means not a keyword.

```
> (mylet ([a #:whoops]) 1)
mylet: expected expression at: #:whoops
```

Also, syntax-parse knows how to report a few kinds of errors without any help:

```
> (mylet ([\begin{array}{lll}{\textrm{a}}&{1}&{2}\end{array}) (* a a))
mylet: unexpected term at: 2
```

There are other kinds of errors, however, that this macro does not handle gracefully:

```
> (mylet (a 1) (+ a 2))
mylet: bad syntax at: (mylet (a 1) (+a 2))
```

It's too much to ask for the macro to respond, "This expression is missing a pair of parentheses around (a 1)." The pattern matcher is not that smart. But it can pinpoint the source of the error: when it encountered a it was expecting what we might call a "binding pair," but that term is not in its vocabulary yet.

To allow syntax-parse to synthesize better errors, we must attach descriptions to the patterns we recognize as discrete syntactic categories. One way of doing that is by defining new syntax classes:

```
> (define-syntax (mylet stx)
    (define-syntax-class binding
        #:description "binding pair"
        (pattern (var:id rhs:expr)))
    (syntax-parse stx
        [(_ (b:binding ...) body ...+)
        #'((lambda (b.var ...) body ...) b.rhs ...)]))
```

Another way is the ~describe pattern form.

Note that we write b.var and b.rhs now. They are the nested attributes formed from the annotated pattern variable $b$ and the attributes var and rhs of the syntax class binding.

Now the error messages can talk about "binding pairs."

```
>(mylet (a 1) (+ a 2))
mylet: expected binding pair at: a
```

Errors are still reported in more specific terms when possible:

```
> (mylet (["a" 1]) (+ a 2))
mylet: expected identifier
    parsing context:
        while parsing binding pair at: "a"
```

There is one other constraint on the legal syntax of mylet. The variables bound by the different binding pairs must be distinct. Otherwise the macro creates an illegal lambda form:

```
> (mylet ([a 1] [a 2]) (+ a a))
lambda: duplicate argument name at: a
```

Constraints such as the distinctness requirement are expressed as side conditions, thus:

```
> (define-syntax (mylet stx)
    (define-syntax-class binding
        #:description "binding pair"
        (pattern (var:id rhs:expr)))
    (syntax-parse stx
        [(_ (b:binding ...) body ...+)
        #:fail-when (check-duplicate-identifier
                        (syntax->list #'(b.var ...)))
            "duplicate variable name"
        #'((lambda (b.var ...) body ...) b.rhs ...)]))
> (mylet ([a 1] [a 2]) (+ a a))
mylet: duplicate variable name at: a
```

The \#:fail-when keyword is followed by two expressions: the condition and the error message. When the condition evaluates to anything but \#f, the pattern fails. Additionally, if the condition evaluates to a syntax object, that syntax object is used to pinpoint the cause of the failure.

Syntax classes can have side conditions, too. Here is the macro rewritten to include another syntax class representing a "sequence of distinct binding pairs."

```
> (define-syntax (mylet stx)
    (define-syntax-class binding
        #:description "binding pair"
        (pattern (var:id rhs:expr)))
    (define-syntax-class distinct-bindings
        #:description "sequence of distinct binding pairs"
        (pattern (b:binding ...)
            #:fail-when (check-duplicate-identifier
                                    (syntax->list #'(b.var ...)))
                                    "duplicate variable name"
                #:with (var ...) #'(b.var ...)
                #:with (rhs ...) #'(b.rhs ...)))
    (syntax-parse stx
        [(_ bs:distinct-bindings . body)
        #'((lambda (bs.var ...) . body) bs.rhs ...)]))
```

Here we've introduced the \#:with clause. A \#:with clause matches a pattern with a computed term. Here we use it to bind var and rhs as attributes of distinct-bindings. By default, a syntax class only exports its patterns' pattern variables as attributes, not their nested attributes.

Alas, so far the macro only implements half of the functionality offered by Racket's let. We must add the "named-let" form. That turns out to be as simple as adding a new clause:

```
> (define-syntax (mylet stx)
    (define-syntax-class binding
        #:description "binding pair"
        (pattern (var:id rhs:expr)))
    (define-syntax-class distinct-bindings
        #:description "sequence of distinct binding pairs"
        (pattern (b:binding ...)
            #:fail-when (check-duplicate-identifier
```

The alternative would be to explicitly declare the attributes of distinct-bindings to include the nested attributes b.var and b.rhs, using the \#:attribute option. Then the macro would refer to bs.b.var and bs.b.rhs.

```
                        (syntax->list #'(b.var ...)))
                        "duplicate variable name"
#:with (var ...) #'(b.var ...)
#:with (rhs ...) #'(b.rhs ...)))
(syntax-parse stx
    [(_ bs:distinct-bindings body ...+)
        #'((lambda (bs.var ...) body ...) bs.rhs ...)]
    [(_ loop:id bs:distinct-bindings body ...+)
    #'(letrec ([loop (lambda (bs.var ...) body ...)])
                (loop bs.rhs ...))]))
```

We are able to reuse the distinct-bindings syntax class, so the addition of the "namedlet" syntax requires only three lines.

But does adding this new case affect syntax-parse's ability to pinpoint and report errors?

```
> (mylet ([a 1] [b 2]) (+ a b))
3
> (mylet (["a" 1]) (add1 a))
mylet: expected identifier
    parsing context:
        while parsing binding pair
        while parsing sequence of distinct binding pairs at: "a"
> (mylet ([a #:whoops]) 1)
mylet: expected expression
    parsing context:
        while parsing binding pair
        while parsing sequence of distinct binding pairs at:
#:whoops
> (mylet ([\begin{array}{lll}{\textrm{a}}&{1}&{2}\end{array}) (* a a))
mylet: unexpected term
    parsing context:
        while parsing binding pair
        while parsing sequence of distinct binding pairs at: 2
> (mylet (a 1) (+ a 2))
mylet: expected binding pair
    parsing context:
        while parsing sequence of distinct binding pairs at: a
> (mylet ([a 1] [a 2]) (+ a a))
mylet: duplicate variable name
    parsing context:
        while parsing sequence of distinct binding pairs at: a
```

The error reporting for the original syntax seems intact. We should verify that the named-let
syntax is working, that syntax-parse is not simply ignoring that clause.

```
> (mylet loop ([a 1] [b 2]) (+ a b))
3
> (mylet loop (["a" 1]) (add1 a))
mylet: expected identifier
    parsing context:
        while parsing binding pair
        while parsing sequence of distinct binding pairs at: "a"
> (mylet loop ([a #:whoops]) 1)
mylet: expected expression
    parsing context:
        while parsing binding pair
        while parsing sequence of distinct binding pairs at:
#:whoops
> (mylet loop ([\begin{array}{lll}{a}&{1}&{2}\end{array}) (* a a))
mylet: unexpected term
    parsing context.
        while parsing binding pair
        while parsing sequence of distinct binding pairs at: 2
> (mylet loop (a 1) (+ a 2))
mylet: expected binding pair
    parsing context:
        while parsing sequence of distinct binding pairs at: a
> (mylet loop ([a 1] [a 2]) (+ a a))
mylet: duplicate variable name
    parsing context:
        while parsing sequence of distinct binding pairs at: a
```

How does syntax-parse decide which clause the programmer was attempting, so it can use it as a basis for error reporting? After all, each of the bad uses of the named-let syntax are also bad uses of the normal syntax, and vice versa. And yet the macro doen not produce errors like "mylet: expected sequence of distinct binding pairs at: loop."

The answer is that syntax-parse records a list of all the potential errors (including ones like loop not matching distinct-binding) along with the progress made before each error. Only the error with the most progress is reported.

For example, in this bad use of the macro,

```
> (mylet loop (["a" 1]) (add1 a))
mylet: expected identifier
    parsing context:
        while parsing binding pair
        while parsing sequence of distinct binding pairs at: "a"
```

there are two potential errors: expected distinct-bindings at loop and expected identifier at "a". The second error occurs further in the term than the first, so it is reported.

For another example, consider this term:

```
> (mylet (["a" 1]) (add1 a))
mylet: expected identifier
    parsing context:
        while parsing binding pair
        while parsing sequence of distinct binding pairs at: "a"
```

Again, there are two potential errors: expected identifier at (["a" 1]) and expected identifier at "a". They both occur at the second term (or first argument, if you prefer), but the second error occurs deeper in the term. Progress is based on a left-to-right traversal of the syntax.

A final example: consider the following:

```
> (mylet ([a 1] [a 2]) (+ a a))
mylet: duplicate variable name
    parsing context:
        while parsing sequence of distinct binding pairs at: a
```

There are two errors again: duplicate variable name at ([ach [a 2]) and expected identifier at ([a 1] [a 2]). Note that as far as syntax-parse is concerned, the progress associated with the duplicate error message is the second term (first argument), not the second occurrence of a. That's because the check is associated with the entire distinctbindings pattern. It would seem that both errors have the same progress, and yet only the first one is reported. The difference between the two is that the first error is from a post-traversal check, whereas the second is from a normal (i.e., pre-traversal) check. A post-traveral check is considered to have made more progress than a pre-traversal check of the same term; indeed, it also has greater progress than any failure within the term.

It is, however, possible for multiple potential errors to occur with the same progress. Here's one example:

```
> (mylet "not-even-close")
mylet: expected identifier or expected sequence of distinct
binding pairs at: "not-even-close"
```

In this case syntax-parse reports both errors.
Even with all of the annotations we have added to our macro, there are still some misuses that defy syntax-parse's error reporting capabilities, such as this example:

```
> (mylet)
mylet: expected more terms at: (mylet)
```

The philosophy behind syntax-parse is that in these situations, a generic error such as "bad syntax" is justified. The use of mylet here is so far off that the only informative error message would include a complete recapitulation of the syntax of mylet. That is not the role of error messages, however; it is the role of documentation.

This section has provided an introduction to syntax classes, side conditions, and progressordered error reporting. But syntax-parse has many more features. Continue to the $\$ 1.2$ "Examples"] section for samples of other features in working code, or skip to the subsequent sections for the complete reference documentation.

### 1.2 Examples

This section provides an extended introduction to syntax/parse as a series of worked examples.

### 1.2.1 Phases and Reusable Syntax Classes

As demonstrated in the $\S 1.1$ "Introduction", the simplest place to define a syntax class is within the macro definition that uses it. But that limits the scope of the syntax class to the one client macro, and it makes for very large macro definitions. Creating reusable syntax classes requires some awareness of the Racket phase level separation. A syntax class defined immediately within a module cannot be used by macros in the same module; it is defined at the wrong phase.

```
> (module phase-mismatch-mod racket
    (require syntax/parse (for-syntax syntax/parse))
    (define-syntax-class foo
        (pattern (a b c)))
    (define-syntax (macro stx)
        (syntax-parse stx
            [(_ f:foo) #'(+ f.a f.b f.c)])))
syntax-parse: not defined as syntax class at: foo
```

In the module above, the syntax class foo is defined at phase level 0 . The reference to foo within macro, however, is at phase level 1, being the implementation of a macro transformer. (Needing to require syntax/parse twice, once normally and once for-syntax is a common warning sign of phase level incompatibility.)

The phase level mismatch is easily remedied by putting the syntax class definition within a begin-for-syntax block:

```
> (module phase-ok-mod racket
    (require (for-syntax syntax/parse))
    (begin-for-syntax
        (define-syntax-class foo
            (pattern (a b c))))
    (define-syntax (macro stx)
            (syntax-parse stx
                [(_ f:foo) #'(+ f.a f.b f.c)])))
```

In the revised module above, $f \circ \circ$ is defined at phase 1 , so it can be used in the implementation of the macro.

An alternative to begin-for-syntax is to define the syntax class in a separate module and require that module for-syntax.

```
> (module stxclass-mod racket
    (require syntax/parse)
    (define-syntax-class foo
            (pattern (a b c)))
        (provide foo))
> (module macro-mod racket
    (require (for-syntax syntax/parse
                                    'stxclass-mod))
    (define-syntax (macro stx)
            (syntax-parse stx
                [(_ f:foo) #'(+ f.a f.b f.c)]))
    (provide macro))
> (require 'macro-mod)
>(macro (1 2 3))
6
```

If a syntax class refers to literal identifiers, or if it computes expressions via syntax templates, then the module containing the syntax class must generally require for-template the bindings referred to in the patterns and templates.

```
> (module arith-keywords-mod racket
    (define-syntax plus (syntax-rules ()))
    (define-syntax times (syntax-rules ()))
    (provide plus times))
> (module arith-stxclass-mod racket
    (require syntax/parse
                (for-template 'arith-keywords-mod
                            racket))
    (define-syntax-class arith
        #:literals (plus times)
```

```
        (pattern n:nat
                #:with expr #'n)
            (pattern (plus a:arith b:arith)
                    #:with expr #'(+ a.expr b.expr))
            (pattern (times a:arith b:arith)
                    #:with expr #'(* a.expr b.expr)))
    (provide arith))
> (module arith-macro-mod racket
    (require (for-syntax syntax/parse
                                    'arith-stxclass-mod)
            'arith-keywords-mod)
    (define-syntax (arith-macro stx)
            (syntax-parse stx
                [(_ a:arith)
                #'(values 'a.expr a.expr)]))
    (provide arith-macro
                            (all-from-out 'arith-keywords-mod)))
> (require 'arith-macro-mod)
> (arith-macro (plus 1 (times 2 3)))
'(+ 1 (* 2 3))
7
```

In 'arith-stxclass-mod, the module 'arith-keywords-mod must be required fortemplate because the keywords are used in phase-0 expressions. Likewise, the module racket must be required for-template because the syntax class contains syntax templates involving + and $*$ (and, in fact, the implicit \#\%app syntax). All of these identifiers (the keywords plus and times; the procedures + and $*$; and the implicit syntax \#\%app) must be bound at "absolute" phase level 0 . Since the module 'arith-stxclass-mod is required with a phase level offset of 1 (that is, for-syntax), it must compensate with a phase level offset of -1 , or for-template.

### 1.2.2 Optional Keyword Arguments

This section explains how to write a macro that accepts (simple) optional keyword arguments. We use the example mycond, which is like Racket's cond except that it takes an optional keyword argument that controls what happens if none of the clauses match.

Optional keyword arguments are supported via head patterns. Unlike normal patterns, which match one term, head patterns can match a variable number of subterms in a list. Some important head-pattern forms are $\sim$ seq, $\sim$ or, and $\sim$ optional.

Here's one way to do it:

```
> (define-syntax (mycond stx)
```

```
        (syntax-parse stx
            [(mycond (~or (~seq #:error-on-fallthrough who:expr) (~seq))
                    clause ...)
            (with-syntax ([error? (if (attribute who) #'#t #'#f)]
                                    [who (or (attribute who) #'#f)])
            #'(mycond* error? who clause ...))]))
> (define-syntax mycond*
    (syntax-rules ()
            [(mycond error? who [question answer] . clauses)
            (if question answer (mycond* error? who . clauses))]
            [(mycond #t who)
            (error who "no clauses matched")]
            [(mycond #f _)
            (void)]))
```

We cannot write \#'who in the macro's right-hand side, because the who attribute does not receive a value if the keyword argument is omitted. Instead we must write (attribute who), which produces $\# \mathrm{f}$ if matching did not assign a value to the attribute.

```
> (mycond [(even? 13) 'blue]
    [(odd? 4) 'red])
> (mycond #:error-on-fallthrough 'myfun
    [(even? 13) 'blue]
    [(odd? 4) 'red])
```

myfun: no clauses matched

There's a simpler way of writing the $\sim$ or pattern above:

```
(~optional (~seq #:error-on-fallthrough who:expr))
```

Yet another way is to introduce a splicing syntax class, which is like an ordinary syntax class but for head patterns.

```
> (define-syntax (mycond stx)
    (define-splicing-syntax-class maybe-fallthrough-option
        (pattern (~seq #:error-on-fallthough who:expr)
            #:with error? #'#t)
        (pattern (~seq)
            #:with error? #'#f
            #:with who #'#f))
    (syntax-parse stx
```

```
[(mycond fo:maybe-fallthrough-option clause ...)
    #'(mycond* fo.error? fo.who clause ...)]))
```

Defining a splicing syntax class also makes it easy to eliminate the case analysis we did before using attribute by defining error? and who as attributes within both of the syntax class's variants. (This is possible to do in the inline pattern version too, using ~and and $\sim$ parse, just less convenient.) Splicing syntax classes also closely parallel the style of grammars in macro documentation.

### 1.2.3 Variants with Uniform Meanings

Syntax classes not only validate syntax, they also extract some measure of meaning from it. From the perspective of meaning, there are essentially two kinds of syntax class. In the first, all of the syntax class's variants have the same kind of meaning. In the second, variants may have different kinds of meaning. This section discusses the first kind, syntax classes with uniform meanings. The next section discusses 1.2.4 "Variants with Varied Meanings"

If all of a syntax class's variants express the same kind of information, that information can be cleanly represented via attributes, and it can be concisely processed using ellipses.

One example of a syntax class with uniform meaning: the init-decl syntax of the class macro. Here is the specification of init-decl:

```
init-decl = id
    | (maybe-renamed)
    | (maybe-renamed default-expr)
maybe-renamed = id
    | (internal-id external-id)
```

The init-decl syntax class has three variants, plus an auxiliary syntax class that has two variants of its own. But all forms of init-decl ultimately carry just three pieces of information: an internal name, an external name, and a default configuration of some sort. The simpler syntactic variants are just abbreviations for the full information.

The three pieces of information determine the syntax class's attributes. It is useful to declare the attributes explicitly using the \#: attributes keyword; the declaration acts both as incode documentation and as a check on the variants.

```
(define-syntax-class init-decl
    #:attributes (internal external default)
    __)
```

Next we fill in the syntactic variants, deferring the computation of the attributes:

```
(define-syntax-class init-decl
    #:attributes (internal external default)
    (pattern ???:id
        __)
    (pattern (???:maybe-renamed)
        __)
    (pattern (???:maybe-renamed ???:expr)
        __))
```

We perform a similar analysis of maybe-renamed:

```
(define-syntax-class maybe-renamed
    #:attributes (internal external)
    (pattern ???:id
                        __)
    (pattern (???:id ???:id)
            __))
```

Here's one straightforward way of matching syntactic structure with attributes for mayberenamed:

```
(define-syntax-class maybe-renamed
    #:attributes (internal external)
    (pattern internal:id
        #:with external #'internal)
    (pattern (internal:id external:id)))
```

Given that definition of maybe-renamed, we can fill in most of the definition of init-decl:

```
(define-syntax-class init-decl
    #:attributes (internal external default)
    (pattern internal:id
            #:with external #:internal
            #:with default ???)
    (pattern (mr:maybe-renamed)
            #:with internal #'mr.internal
            #:with external #'mr.external
            #:with default ???)
    (pattern (mr:maybe-renamed default0:expr)
            #:with internal #'mr.internal
            #:with external #'mr.external
            #:with default ???))
```

At this point we realize we have not decided on a representation for the default configuration. In fact, it is an example of syntax with varied meanings (aka sum or disjoint union).

The following section discusses representation options in greater detail; for the sake of completeness, we present one of them here.

There are two kinds of default configuration. One indicates that the initialization argument is optional, with a default value computed from the given expression. The other indicates that the initialization argument is mandatory. We represent the variants as a (syntax) list containing the default expression and as the empty (syntax) list, respectively. More precisely:

```
(define-syntax-class init-decl
    #:attributes (internal external default)
    (pattern internal:id
            #:with external #:internal
            #:with default #'())
    (pattern (mr:maybe-renamed)
            #:with internal #'mr.internal
            #:with external #'mr.external
            #:with default #'())
    (pattern (mr:maybe-renamed default0:expr)
            #:with internal #'mr.internal
            #:with external #'mr.external
            #:with default #'(default0)))
```

Another way to look at this aspect of syntax class design is as the algebraic factoring of sums-of-products (concrete syntax variants) into products-of-sums (attributes and abstract syntax variants). The advantages of the latter form are the "dot" notation for data extraction, avoiding or reducing additional case analysis, and the ability to concisely manipulate sequences using ellipses.

## 1.2 . Variants with Varied Meanings

As explained in the previous section, the meaning of a syntax class can be uniform, or it can be varied; that is, different instances of the syntax class can carry different kinds of information. This section discusses the latter kind of syntax class.

A good example of a syntax class with varied meanings is the for-clause of the for family of special forms.

```
for-clause = [id seq-expr]
    | [(id ...) seq-expr]
    | #:when guard-expr
```

The first two variants carry the same kind of information; both consist of identifiers to bind and a sequence expression. The third variant, however, means something totally different: a condition that determines whether to continue the current iteration of the loop, plus a change in scoping for subsequent seq-exprs. The information of a for-clause must be
represented in a way that a client macro can do further case analysis to distinguish the "bind variables from a sequence" case from the "skip or continue this iteration and enter a new scope" case.

This section discusses two ways of representing varied kinds of information.

## Syntactic Normalization

One approach is based on the observation that the syntactic variants already constitute a representation of the information they carry. So why not adapt that representation, removing redundancies and eliminating simplifying the syntax to make subsequent re-parsing trivial.

```
(define-splicing-syntax-class for-clause
    #:attribute (norm)
    (pattern [var:id seq:expr]
            #:with norm #'[(var) seq])
    (pattern [(var:id ...) seq:expr]
            #:with norm #'[(var ...) seq])
    (pattern (~seq #:when guard:expr)
            #:with norm #'[#:when guard]))
```

First, note that since the \#: when variant consists of two separate terms, we define forclause as a splicing syntax class. Second, that kind of irregularity is just the sort of thing we'd like to remove so we don't have to deal with it again later. Thus we represent the normalized syntax as a single term beginning with either a sequence of identifiers (the first two cases) or the keyword \#: when (the third case). The two normalized cases are easy to process and easy to tell apart. We have also taken the opportunity to desugar the first case into the second.

A normalized syntactic representation is most useful when the subsequent case analysis is performed by syntax-parse or a similar form.

## Non-syntax-valued Attributes

When the information carried by the syntax is destined for complicated processing by Racket code, it is often better to parse it into an intermediate representation using idiomatic Racket data structures, such as lists, hashes, structs, and even objects.

Thus far we have only used syntax pattern variables and the \#:with keyword to bind attribues, and the values of the attributes have always been syntax. To bind attributes to values other than syntax, use the \#: attr keyword.

```
; A ForClause is either
; - (bind-clause (listof identifier) syntax)
; - (when-clause syntax)
(struct bind-clause (vars seq-expr))
(struct when-clause (guard))
```

```
(define-splicing-syntax-class for-clause
    #:attributes (ast)
    (pattern [var:id seq:expr]
                #:attr ast (bind-clause (list #'var) #'seq))
    (pattern [(var:id ...) seq:expr]
                        #:attr ast (bind-clause (syntax->list #'(var ...))
                            #'seq))
    (pattern (~seq #:when guard:expr)
            #:attr ast (when-clause #'guard)))
```

Be careful! If we had used \#:with instead of \#: attr, the \#f would have been coerced to a syntax object before being matched against the pattern default.

Attributes with non-syntax values cannot be used in syntax templates. Use the attribute form to get the value of an attribute.

### 1.2.5 More Keyword Arguments

This section shows how to express the syntax of struct's optional keyword arguments using syntax-parse patterns.

The part of struct's syntax that is difficult to specify is the sequence of struct options. Let's get the easy part out of the way first.

```
> (define-splicing-syntax-class maybe-super
    (pattern (~seq super:id))
    (pattern (~seq)))
> (define-syntax-class field-option
    (pattern #:mutable)
    (pattern #:auto))
> (define-syntax-class field
    (pattern field:id
        #:with (option ...) '())
    (pattern [field:id option:field-option ...]))
```

Given those auxiliary syntax classes, here is a first approximation of the main pattern, including the struct options:

```
(struct name:id super:maybe-super (field:field ...)
    (~or (~seq #:mutable)
        (~seq #:super super-expr:expr)
            (~seq #:inspector inspector:expr)
```

```
    (~seq #:auto-value auto:expr)
    (~seq #:guard guard:expr)
    (~seq #:property prop:expr prop-val:expr)
    (~seq #:transparent)
    (~seq #:prefab)
    (~seq #:constructor-name constructor-name:id)
    (~seq #:extra-constructor-name extra-constructor-name:id)
    (~seq #:omit-define-syntaxes)
    (~seq #:omit-define-values))
...)
```

The fact that expr does not match keywords helps in the case where the programmer omits a keyword's argument; instead of accepting the next keyword as the argument expression, syntax-parse reports that an expression was expected.

There are two main problems with the pattern above:

- There's no way to tell whether a zero-argument keyword like \#: mutable was seen.
- Some options, like \#: mut able, should appear at most once.

The first problem can be remedied using $\sim$ and patterns to bind a pattern variable to the keyword itself, as in this sub-pattern:

```
(~seq (~and #:mutable mutable-kw))
```

The second problem can be solved using repetition constraints:

```
(struct name:id super:maybe-super (field:field ...)
    (~or (~optional (~seq (~and #:mutable mutable-kw)))
        (~optional (~seq #:super super-expr:expr))
        (~optional (~seq #:inspector inspector:expr))
        (~optional (~seq #:auto-value auto:expr))
        (~optional (~seq #:guard guard:expr))
        (~seq #:property prop:expr prop-val:expr)
        (~optional (~seq (~and #:transparent transparent-kw)))
        (~optional (~seq (~and #:prefab prefab-kw)))
        (~optional (~seq #:constructor-name constructor-name:id))
        (~optional
            (~seq #:extra-constructor-name extra-constructor-
name:id))
            (~optional
                (~seq (~and #:omit-define-syntaxes omit-def-stxs-kw)))
```

```
    (~optional (~seq (~and #:omit-define-values omit-def-
vals-kw))))
    ...)
```

The $\sim$ optional repetition constraint indicates that an alternative can appear at most once. (There is a ~once form that means it must appear exactly once.) In struct's keyword options, only \#: property may occur any number of times.

There are still some problems, though. Without additional help, ~optional does not report particularly good errors. We must give it the language to use, just as we had to give descriptions to sub-patterns via syntax classes. Also, some related options are mutually exclusive, such as \#: inspector, \#:transparent, and \#: prefab.

```
(struct name:id super:maybe-super (field:field ...)
    (~or (~optional
            (~or (~seq #:inspector inspector:expr)
                    (~seq (~and #:transparent transparent-kw))
                    (~seq (~and #:prefab prefab-kw)))
            #:name "#:inspector, #:transparent, or #:prefab option")
            (~optional (~seq (~and #:mutable mutable-kw))
                    #:name "#:mutable option")
            (~optional (~seq #:super super-expr:expr)
                    #:name "#:super option")
            (~optional (~seq #:auto-value auto:expr)
                    #:name "#:auto-value option")
            (~optional (~seq #:guard guard:expr)
                        #:name "#:guard option")
            (~seq #:property prop:expr prop-val:expr)
            (~optional (~seq #:constructor-name constructor-name:id)
                            #:name "#:constructor-name option")
            (~optional
                        (~seq #:extra-constructor-name extra-constructor-
name:id)
            #:name "#:extra-constructor-name option")
            (~optional (~seq (~and #:omit-define-syntaxes omit-def-
stxs-kw))
                        #:name "#:omit-define-syntaxes option")
            (~optional (~seq (~and #:omit-define-values omit-def-
vals-kw))
                            #:name "#:omit-define-values option"))
    ...)
```

Here we have grouped the three incompatible options together under a single $\sim$ optional constraint. That means that at most one of any of those options is allowed. We have given names to the optional clauses. See $\sim$ optional for other customization options.

Note that there are other constraints that we have not represented in the pattern. For example, \# : prefab is also incompatible with both \#: guard and \#: property. Repetition constraints cannot express arbitrary incompatibility relations. The best way to handle such constraints is with a side condition using \#:fail-when.

### 1.2.6 Contracts on Macro Sub-expressions

Just as procedures often expect certain kinds of values as arguments, macros often have expectations about the expressions they are given. And just as procedures express those expectations via contracts, so can macros, using the expr/c syntax class.

For example, here is a macro myparameterize that behaves like parameterize but enforces the parameter? contract on the parameter expressions.

```
> (define-syntax (myparameterize stx)
    (syntax-parse stx
            [(_ ((p v:expr) ...) body:expr)
            #:declare p (expr/c #'parameter?
                                    #:name "parameter argument")
            #'(parameterize ([p.c v] ...) body)]))
> (myparameterize ([current-input-port
                                    (open-input-string "(1 2 3)")])
    (read))
,(1 2 3)
> (myparameterize (['whoops 'something])
    'whatever)
parameter argument of myparameterize: broke its contract
    promised: parameter?
    produced: 'whoops
    in: parameter?
    contract from: program
    blaming: program
    at: eval:61.0
```

Important: Make sure when using expr/c to use the $c$ attribute. If the macro above had used $p$ in the template, the expansion would have used the raw, unchecked expressions. The expr/c syntax class does not change how pattern variables are bound; it only computes an attribute that represents the checked expression.

### 1.3 Parsing Syntax

This section describes syntax-parse, the syntax/parse library's facility for parsing syntax. Both syntax-parse and the specification facility, syntax classes, use a common lan-
guage of syntax patterns, which is described in detail in §1.5 "Syntax Patterns"
Two parsing forms are provided: syntax-parse and syntax-parser.

```
(syntax-parse stx-expr parse-option ... clause ...+)
    parse-option = #:context context-expr
            | #:literals (literal ...)
            | #:datum-literals (datum-literal ...)
            | #:literal-sets (literal-set ...)
            | #:conventions (convention-id ...)
            | #:local-conventions (convention-rule ...)
            | #:disable-colon-notation
        literal = literal-id
            | (pattern-id literal-id)
    | (pattern-id literal-id #:phase phase-expr)
        datum-literal = literal-id
                            | (pattern-id literal-id)
        literal-set = literal-set-id
                        | (literal-set-id literal-set-option ...)
literal-set-option = #:at context-id
                            | #:phase phase-expr
        clause = (syntax-pattern pattern-directive ... body ...+)
stx-expr : syntax?
context-expr : syntax?
phase-expr : (or/c exact-integer? #f)
```

Evaluates stx-expr, which should produce a syntax object, and matches it against the clauses in order. If some clause's pattern matches, its attributes are bound to the corresponding subterms of the syntax object and that clause's side conditions and expr is evaluated. The result is the result of expr.

Each clause consists of a syntax pattern, an optional sequence of pattern directives, and a non-empty sequence of body forms.

If the syntax object fails to match any of the patterns (or all matches fail the corresponding clauses' side conditions), a syntax error is raised.

The following options are supported:

```
#:context context-expr
    context-expr : syntax?
```

When present, context-expr is used in reporting parse failures; otherwise stx-expr is used. The current-syntax-context parameter is also set to the value of context-expr.

Examples:

```
> (syntax-parse #'(a b 3)
                    [(x:id ...) ,ok])
a: expected identifier at: }
> (syntax-parse #'(a b 3)
                    #:context #'(lambda (a b 3) (+ a b))
                    [(x:id ...) 'ok])
```

lambda: expected identifier at: 3
\#:literals (literal ...)
literal = literal-id
| (pattern-id literal-id)
| (pattern-id literal-id \#:phase phase-expr)
phase-expr : (or/c exact-integer? \#f)

The \#:literals option specifies identifiers that should be treated as literals rather than pattern variables. An entry in the literals list has two components: the identifier used within the pattern to signify the positions to be matched (pattern-id), and the identifier expected to occur in those positions (literal-id). If the entry is a single identifier, that identifier is used for both purposes.

If the \#:phase option is given, then the literal is compared at phase phaseexpr. Specifically, the binding of the literal-id at phase phase-expr must match the input's binding at phase phase-expr.
In other words, the syntax-patterns are interpreted as if each occurrence of pattern-id were replaced with the following pattern:
(~literal literal-id \#:phase phase-expr)
\#:datum-literals (datum-literal ...)

```
datum-literal = literal-id
    | (pattern-id literal-id)
```

Like \#:literals, but the literals are matched as symbols instead of as identifiers.
In other words, the syntax-patterns are interpreted as if each occurrence of pattern-id were replaced with the following pattern:
(~datum literal-id)

```
#:literal-sets (literal-set ...)
    literal-set = literal-set-id
    | (literal-set-id literal-set-option ...)
literal-set-option = #:at lctx
    | #:phase phase-expr
    phase-expr : (or/c exact-integer? #f)
```

Many literals can be declared at once via one or more literal sets, imported with the \#:literal-sets option. See literal sets for more information.
If the \#: at keyword is given, the lexical context of the lctx term is used to determine which identifiers in the patterns are treated as literals; this option is useful primarily for macros that generate syntax-parse expressions.
\#: conventions (conventions-id ...)

Imports conventions that give default syntax classes to pattern variables that do not explicitly specify a syntax class.
\#: local-conventions (convention-rule ...)

Uses the conventions specified. The advantage of \#: local-conventions over \#: conventions is that local conventions can be in the scope of syntax-class parameter bindings. See the section on conventions for examples.
| \#:disable-colon-notation

Suppresses the "colon notation" for annotated pattern variables.

Examples:

```
    > (syntax-parse #'(a b c)
    [(x:y ...) 'ok])
    syntax-parse: not defined as syntax class at: y
    > (syntax-parse #'(a b c) #:disable-colon-notation
    [(x:y ...) ,ok])
    ,ok
|(syntax-parser parse-option ... clause ...+)
```

Like syntax-parse, but produces a matching procedure. The procedure accepts a single argument, which should be a syntax object.

```
(define/syntax-parse syntax-pattern pattern-directive ... stx-expr)
    stx-expr : syntax?
```

Definition form of syntax-parse. That is, it matches the syntax object result of stxexpr against syntax-pattern and creates pattern variable definitions for the attributes of syntax-pattern.

## Examples:

```
> (define/syntax-parse ((~seq kw:keyword arg:expr) ...)
    #'(#:a 1 #:b 2 #:c 3))
> #'(kw ...)
#<syntax:67:0 (#:a #:b #:c)>
```

Compare with define/with-syntax, a similar definition form that uses the simpler syntax-case patterns.

### 1.4 Specifying Syntax with Syntax Classes

Syntax classes provide an abstraction mechanism for syntax patterns. Built-in syntax classes are supplied that recognize basic classes such as identifier and keyword. Programmers can compose basic syntax classes to build specifications of more complex syntax, such as lists of distinct identifiers and formal arguments with keywords. Macros that manipulate the same syntactic structures can share syntax class definitions.

```
(define-syntax-class name-id stxclass-option ...
    stxclass-variant ...+)
(define-syntax-class (name-id . kw-formals) stxclass-option ...
    stxclass-variant ...+)
```

```
stxclass-option = #:attributes (attr-arity-decl ...)
    | #:description description-expr
    | #:opaque
    | #:commit
    | #:no-delimit-cut
    | #:literals (literal-entry ...)
    | #:datum-literals (datum-literal-entry ...)
    | #:literal-sets (literal-set ...)
    | #:conventions (convention-id ...)
    | #:local-conventions (convention-rule ...)
    | #:disable-colon-notation
attr-arity-decl = attr-name-id
    | (attr-name-id depth)
stxclass-variant = (pattern syntax-pattern pattern-directive ...)
    description-expr : (or/c string? #f)
```

Defines name-id as a syntax class, which encapsulates one or more single-term patterns.
A syntax class may have formal parameters, in which case they are bound as variables in the body. Syntax classes support optional arguments and keyword arguments using the same syntax as lambda. The body of the syntax-class definition contains a non-empty sequence of pattern variants.

The following options are supported:

```
#:attributes (attr-arity-decl ...)
attr-arity-decl = attr-id
    | (attr-id depth)
```

Declares the attributes of the syntax class. An attribute arity declaration consists of the attribute name and optionally its ellipsis depth (zero if not explicitly specified).
If the attributes are not explicitly listed, they are inferred as the set of all pattern variables occurring in every variant of the syntax class. Pattern variables that occur at different ellipsis depths are not included, nor are nested attributes from annotated pattern variables.
\#:description description-expr

```
description-expr : (or/c string? #f)
```

The description argument is evaluated in a scope containing the syntax class's parameters. If the result is a string, it is used in error messages involving the syntax class. For example, if a term is rejected by the syntax class, an error of the form "expected description" may be synthesized. If the result is \#f, the syntax class is skipped in the search for a description to report.
If the option is not given, the name of the syntax class is used instead.

```
#: opaque
```

Indicates that errors should not be reported with respect to the internal structure of the syntax class.
\#: commit

Directs the syntax class to "commit" to the first successful match. When a variant succeeds, all choice points within the syntax class are discarded. See also $\sim$ commit.
| \#:no-delimit-cut

By default, a cut ( $\sim$ !) within a syntax class only discards choice points within the syntax class. That is, the body of the syntax class acts as though it is wrapped in a ~delimit-cut form. If \#:no-delimit-cut is specified, a cut may affect choice points of the syntax class's calling context (another syntax class's patterns or a syntax-parse form).

It is an error to use both \#: commit and \#:no-delimit-cut.
| \#:literals (literal-entry ...)
| \#: datum-literals (datum-literal-entry ...)
\#: literal-sets (literal-set ...)

```
#:conventions (convention-id ...)
```

Declares the literals and conventions that apply to the syntax class's variant patterns and their immediate \#:with clauses. Patterns occuring within subexpressions of the syntax class (for example, on the right-hand side of a \#:fail-when clause) are not affected.

These options have the same meaning as in syntax-parse.

Each variant of a syntax class is specified as a separate pattern-form whose syntax pattern is a single-term pattern.

```
(define-splicing-syntax-class name-id stxclass-option ...
    stxclass-variant ...+)
(define-splicing-syntax-class (name-id kw-formals) stxclass-option ...
    stxclass-variant ...+)
```

Defines name-id as a splicing syntax class, analogous to a syntax class but encapsulating head patterns rather than single-term patterns.

The options are the same as for define-syntax-class.
Each variant of a splicing syntax class is specified as a separate pattern-form whose syntax pattern is a head pattern.
| (pattern syntax-pattern pattern-directive ...)

Used to indicate a variant of a syntax class or splicing syntax class. The variant accepts syntax matching the given syntax pattern with the accompanying pattern directives.

When used within define-syntax-class, syntax-pattern should be a single-term pattern; within define-splicing-syntax-class, it should be a head pattern.

The attributes of the variant are the attributes of the pattern together with all attributes bound by \#:with clauses, including nested attributes produced by syntax classes associated with the pattern variables.

### 1.4.1 Pattern Directives

Both the parsing forms and syntax class definition forms support pattern directives for annotating syntax patterns and specifying side conditions. The grammar for pattern directives follows:

```
pattern-directive = #:declare pattern-id stxclass maybe-role
```

```
| #:with syntax-pattern expr
| #:attr attr-arity-decl expr
| #:fail-when condition-expr message-expr
| #:fail-unless condition-expr message-expr
| #:when condition-expr
| #:do [def-or-expr ...]
```

```
#:declare pvar-id stxclass maybe-role
    stxclass = syntax-class-id
            | (syntax-class-id arg ...)
maybe-role =
    | #:role role-expr
```

Associates pvar-id with a syntax class and possibly a role, equivalent to replacing each occurrence of pvar-id in the pattern with ( $\sim$ var pvar-id stxclass maybe-role). The second form of stxclass allows the use of parameterized syntax classes, which cannot be expressed using the "colon" notation. The args are evaluated in the scope where the pvar-id occurs in the pattern. Keyword arguments are supported, using the same syntax as in \#\%app.
\#:with syntax-pattern stx-expr

Evaluates the stx-expr in the context of all previous attribute bindings and matches it against the pattern. If the match succeeds, the pattern's attributes are added to environment for the evaluation of subsequent side conditions. If the \#: with match fails, the matching process backtracks. Since a syntax object may match a pattern in several ways, backtracking may cause the same clause to be tried multiple times before the next clause is reached.
If the value of stx-expr is not a syntax object, it is implicitly converted to a syntax object. If the the conversion would produce $3 D$ syntax -that is, syntax that contains unwritable values such as procedures, non-prefab structures, etcthen an exception is raised instead.
\#:attr attr-arity-decl expr

Evaluates the expr in the context of all previous attribute bindings and binds it to the given attribute. The value of expr need not be, or even contain, syntaxsee attribute for details.

```
#:fail-when condition-expr message-expr
    message-expr : (or/c string? #f)
```

Evaluates the condition-expr in the context of all previous attribute bindings. If the value is any true value (not \#f), the matching process backtracks (with the given message); otherwise, it continues. If the value of the condition expression is a syntax object, it is indicated as the cause of the error.

If the message-expr produces a string it is used as the failure message; otherwise the failure is reported in terms of the enclosing descriptions.

```
#:fail-unless condition-expr message-expr
    message-expr : (or/c string? #f)
```

Like \#:fail-when with the condition negated.

```
#:when condition-expr
```

Evaluates the condition-expr in the context of all previous attribute bindings. If the value is \#f, the matching process backtracks. In other words, \#: when is like \#: fail-unless without the message argument.
\#:do [def-or-expr ...]

Takes a sequence of definitions and expressions, which may be intermixed, and evaluates them in the scope of all previous attribute bindings. The names bound by the definitions are in scope in the expressions of subsequent patterns and clauses.

There is currently no way to bind attributes using a \#: do block. It is an error to shadow an attribute binding with a definition in a \#: do block.

### 1.4.2 Pattern Variables and Attributes

An attribute is a name bound by a syntax pattern. An attribute can be a pattern variable itself, or it can be a nested attribute bound by an annotated pattern variable. The name of a nested attribute is computed by concatenating the pattern variable name with the syntax class's exported attribute's name, separated by a dot (see the example below).

Attributes can be used in two ways: with the attribute form, and inside syntax templates via syntax, quasisyntax, etc. Attribute names cannot be used directly as expressions; that is, attributes are not variables.

A syntax-valued attribute is an attribute whose value is a syntax object, a syntax list of the appropriate ellipsis depth, or a tree containing promises that when completely forced produces a suitable syntax object or syntax list. Syntax-valued attributes can be used within syntax, quasisyntax, etc as part of a syntax template. If an attribute is used inside a syntax template but it is not syntax-valued, an error is signaled.

The value of an attribute is not required to be syntax. Non-syntax-valued attributes can be used to return a parsed representation of a subterm or the results of an analysis on the subterm. A non-syntax-valued attribute should be bound using the \#: attr directive or a ~bind pattern; \#:with and $\sim$ parse will convert the right-hand side to a (possibly 3D) syntax object.

## Example:

```
> (define-syntax-class table
    (pattern ((key value) ...)
            #:attr hashtable
                            (for/hash ([k (syntax->datum #'(key . ..))]
                                [v (syntax->datum #'(value ...))])
                                (values k v))
            #:attr [sorted-kv 1]
                        (delay
                        (printf "sorting!\n")
                        (sort (syntax->list #'((key value) ...))
                            <
                            #:key (lambda (kv) (cadr (syntax-
>(atum kv)))))))
```

The table syntax class provides four attributes: key, value, hashtable, and sorted-kv. The hashtable attribute has ellipsis depth 0 and the rest have depth 1 ; all but hashtable are syntax-valued. The sorted-kv attribute's value is a promise; it will be automatically forced if used in a syntax template.

Syntax-valued attributes can be used in syntax templates:

```
> (syntax-parse #'(() a 3) (b 2) (c 1))
    [t:table
    #'(t.key ...)])
#<syntax:69:0 (a b c)>
> (syntax-parse #'(() a 3) (b 2) (c 1))
    [t:table
        #'(t.sorted-kv ...)])
sorting!
#<syntax:70:0 ((c 1) (b 2) (a 3))>
```

But non-syntax-valued attributes cannot:

```
> (syntax-parse #'((a 3) (b 2) (c 1))
    [t:table
        #'t.hashtable])
t.hashtable: attribute is bound to non-syntax value
    value:'#hash((a.3) (b . 2) (c. 1)) at: t.hashtable
```

Use the attribute form to get the value of an attribute (syntax-valued or not).

```
> (syntax-parse #'((a 1) (b 2) (c 3))
    [t:table
            (attribute t.hashtable)])
,#hash((a . 1) (b . 2) (c . 3))
> (syntax-parse #'((a 3) (b 2) (c 1))
    [t:table
            (attribute t.sorted-kv)])
#<promise:sorted-kv161>
```

Every attribute has an associated ellipsis depth that determines how it can be used in a syntax template (see the discussion of ellipses in syntax). For a pattern variable, the ellipsis depth is the number of ellipses the pattern variable "occurs under" in the pattern. An attribute bound by \#: attr has depth 0 unless declared otherwise. For a nested attribute the depth is the sum of the annotated pattern variable's depth and the depth of the attribute exported by the syntax class.

Consider the following code:

```
(define-syntax-class quark
    (pattern (a b ...)))
(syntax-parse some-term
    [(x (y:quark ...) ... z:quark)
        some-code])
```

The syntax class quark exports two attributes: a at depth 0 and $b$ at depth 1 . The syntaxparse pattern has three pattern variables: $x$ at depth $0, y$ at depth 2 , and $z$ at depth 0 . Since $x$ and $y$ are annotated with the quark syntax class, the pattern also binds the following nested attributes: y.a at depth $2, \mathrm{y} . \mathrm{b}$ at depth $3, \mathrm{z} . \mathrm{a}$ at depth 0 , and $\mathrm{z} . \mathrm{b}$ at depth 1 .

An attribute's ellipsis nesting depth is not a guarantee that it is syntax-valued. In particular, $\sim$ or and $\sim$ optional patterns may result in attributes with fewer than expected levels of list nesting, and \#: attr and ~bind can be used to bind attributes to arbitrary values.

## Example:

[^0]```
        [(~or (x:id ...) _)
    (attribute x)])
    #f
|(attribute attr-id)
```

Returns the value associated with the attribute named attr-id. If attr-id is not bound as an attribute, an error is raised.

### 1.5 Syntax Patterns

The grammar of syntax patterns used by syntax/parse facilities is given in the following table. There are four main kinds of syntax pattern:

- single-term patterns, abbreviated $S$-pattern
- head patterns, abbreviated $H$-pattern
- ellipsis-head patterns, abbreviated EH-pattern
- action patterns, abbreviated A-pattern

A fifth kind, list patterns (abbreviated $L$-pattern), is a just a syntactically restricted subset of single-term patterns.

When a special form in this manual refers to syntax-pattern (eg, the description of the syntax-parse special form), it means specifically single-term pattern.

```
S-pattern = pvar-id
    | pvar-id:syntax-class-id
    | literal-id
    | (~var s- id)
    | (~var}\mp@subsup{}{}{\mathrm{ s+ }}\mathrm{ id syntax-class-id maybe-role)
    | (~\mp@subsup{var}{}{\mathrm{ s+ }}\mathrm{ id (syntax-class-id arg ...) maybe-role)}
    | (~literal literal-id maybe-phase)
    | atomic-datum
    | (~datum datum)
    | (H-pattern . S-pattern)
    | (A-pattern . S-pattern)
    | (EH-pattern ... . S-pattern)
    | (H-pattern ...+ . S-pattern)
    | (~and}\mp@subsup{}{}{s}\mathrm{ proper-S/A-pattern ...+)
    | (~ors S-pattern ...+)
    | (~not S-pattern)
    | #(pattern-part ...)
```

```
    | #s(prefab-struct-key pattern-part ...)
    | #&S-pattern
    | (~rest S-pattern)
    | (~describes maybe-opaque maybe-role expr S-pattern)
    | (~commits S-pattern)
    | (~delimit-cut's S-pattern)
    | A-pattern
L-pattern = ()
    | (A-pattern . L-pattern)
    | (H-pattern . L-pattern)
    | (EH-pattern ... . L-pattern)
    | (H-pattern ...+ . L-pattern)
    | (~rest L-pattern)
H-pattern = pvar-id:splicing-syntax-class-id
    | (~varh id splicing-syntax-class-id maybe-role)
    | (~\mp@subsup{var}{}{h}}\mathrm{ id (splicing-syntax-class-id arg ...)
                maybe-role)
    | (~seq. L-pattern)
    | (~and h proper-H/A-pattern ...+)
    | (~orh H-pattern ...+)
    | (~optional h H-pattern maybe-optional-option)
    | (~describe h maybe-opaque maybe-role expr H-pattern)
    | (~commith H-pattern)
    | (~delimit-cuth H-pattern)
    | (~peek H-pattern)
    | (~peek-not H-pattern)
    | proper-S-pattern
EH-pattern = (~or eh EH-pattern ...)
    (~once H-pattern once-option ...)
    | (~optional eh H-pattern optional-option ...)
    | (~between H min-number max-number between-option)
    | H-pattern
A-pattern = ~!
    | (~bind [attr-arity-decl expr] ...)
    | (~fail maybe-fail-condition maybe-message-expr)
    | (~parse S-pattern stx-expr)
    | (~and }\mp@subsup{}{}{\textrm{a}}\mathrm{ A-pattern ...+)
    | (~do defn-or-expr ...)
```

proper-S-pattern $=$ a $S$-pattern that is not a $A$-pattern
proper-H-pattern $=$ a $H$-pattern that is not a $S$-pattern
The following pattern keywords can be used in multiple pattern variants:
~var

One of $\sim \operatorname{var}^{s-}, \sim \operatorname{var}^{\mathrm{S}+}$, or $\sim \operatorname{var}^{\mathrm{h}}$.
\| and

One of $\sim$ and $^{\mathrm{s}}, \sim \operatorname{and}^{\mathrm{h}}$, or $\sim \operatorname{and}^{\mathrm{a}}:$

- $\sim \operatorname{and}^{\mathrm{a}}$ if all of the conjuncts are action patterns
- $\sim \operatorname{and}^{\mathrm{h}}$ if any of the conjuncts is a proper head pattern
- $\sim a n d^{\text {s }}$ otherwise
~or

One of $\sim \mathrm{or}^{\mathrm{s}}, \sim \operatorname{or}^{\mathrm{h}}$, or $\sim \mathrm{or}^{\text {eh }}$ :

- $\sim r^{\text {eh }}$ if the pattern occurs directly before ellipses (. . .) or immediately within another $\sim$ or $^{\text {eh }}$ pattern
- $\sim o r^{h}$ if any of the disjuncts is a proper head pattern
- $\sim o r^{\text {s }}$ otherwise
\| describe

One of $\sim$ describe $^{s}$ or $\sim$ describe ${ }^{h}$ :

- $\sim$ describe $^{\mathrm{h}}$ if the subpattern is a proper head pattern
- $\sim$ describe ${ }^{\text {s }}$ otherwise
|~commit

One of $\sim$ commit $^{\text {s }}$ or $\sim$ commit $^{\text {h }: ~}$

- $\sim$ commit $^{\mathrm{h}}$ if the subpattern is a proper head pattern
- $\sim$ commit $^{\text {s }}$ otherwise
\| ~delimit-cut

One of $\sim$ delimit-cut ${ }^{s}$ or $\sim$ delimit-cut ${ }^{\text {h }}$ :

- $\sim$ delimit-cut ${ }^{h}$ if the subpattern is a proper head pattern
- ~delimit-cut ${ }^{\text {s }}$ otherwise
|~optional

One of $\sim$ optional $^{\text {h }}$ or $\sim$ optional $^{\text {eh }}$ :

- $\sim$ optional ${ }^{\text {eh }}$ if it is an immediate disjunct of a $\sim r^{\text {eh }}$ pattern
- $\sim$ optional ${ }^{\text {h }}$ otherwise

### 1.5.1 Single-term Patterns

A single-term pattern (abbreviated $S$-pattern) is a pattern that describes a single term. These are like the traditional patterns used in syntax-rules and syntax-case, but with additional variants that make them more expressive.
"Single-term" does not mean "atomic"; a single-term pattern can have complex structure, and it can match terms that have many parts. For example, (17 . . .) is a single-term pattern that matches any term that is a proper list of repeated 17 numerals.

A proper single-term pattern is one that is not an action pattern.
The list patterns (for "list pattern") are single-term patterns having a restricted structure that guarantees that they match only terms that are proper lists.

Here are the variants of single-term pattern:
|id

An identifier can be either a pattern variable, an annotated pattern variable, or a literal:

- If id is the "pattern" name of an entry in the literals list, it is a literal pattern that behaves like ( $\sim$ literal id).

Examples:

```
> (syntax-parse #'(define x 12)
    #:literals (define)
    [(define var:id body:expr) 'ok])
,ok
> (syntax-parse #'(lambda x 12)
    #:literals (define)
    [(define var:id body:expr) 'ok])
lambda: expected the identifier 'define' at: lambda
> (syntax-parse #'(define x 12)
    #:literals ([def define])
        [(def var:id body:expr) 'ok])
,ok
> (syntax-parse #'(lambda x 12)
        #:literals ([def define])
        [(def var:id body:expr) 'ok])
lambda: expected the identifier 'define' at: lambda
```

- If id is of the form pvar-id:syntax-class-id (that is, two names joined by a colon character), it is an annotated pattern variable, and the pattern is equivalent to ( $\sim$ var pvar-id syntax-class-id).
Examples:

```
> (syntax-parse #'a
    [var:id (syntax-e #'var)])
'a
> (syntax-parse #'12
    [var:id (syntax-e #'var)])
?: expected identifier at: 12
> (define-syntax-class two
    #:attributes (x y)
    (pattern (x y)))
> (syntax-parse #'(a b)
    [t:two (syntax->datum #'(t t.x t.y))])
,((a b) a b)
> (syntax-parse #'(a b)
    [t
        #:declare t two
        (syntax->datum #'(t t.x t.y))])
,((a b) a b)
```

Note that an id of the form : syntax-class-id is legal; see the discussion of a $\sim \operatorname{var}^{\mathrm{s+}}$ form with a zero-length pvar-id.

- Otherwise, id is a pattern variable, and the pattern is equivalent to ( $\sim \operatorname{var}$ id).

```
(~var pvar-id)
```

A pattern variable. If pvar-id has no syntax class (by \#:convention), the pattern variable matches anything. The pattern variable is bound to the matched subterm, unless the pattern variable is the wildcard (_), in which case no binding occurs.

If pvar-id does have an associated syntax class, it behaves like an annotated pattern variable with the implicit syntax class inserted.

```
(~var pvar-id syntax-class-use maybe-role)
syntax-class-use = syntax-class-id
    | (syntax-class-id arg ...)
        maybe-role =
            | #:role role-expr
    role-expr : (or/c string? #f)
```

An annotated pattern variable. The pattern matches only terms accepted by syntax-class-id (parameterized by the args, if present).
In addition to binding pvar-id, an annotated pattern variable also binds nested attributes from the syntax class. The names of the nested attributes are formed by prefixing pvar-id. (that is, pvar-id followed by a "dot" character) to the name of the syntax class's attribute.
If pvar-id is _, no attributes are bound. If pvar-id is the zero-length identifier (||), then pvar-id is not bound, but the nested attributes of syntax-classuse are bound without prefixes.
If role-expr is given and evaluates to a string, it is combined with the syntax class's description in error messages.
Examples:

```
> (syntax-parse #'a
    [(~var var id) (syntax-e #'var)])
        'a
        > (syntax-parse #'12
            [(~var var id) (syntax-e #'var)])
        ?: expected identifier at: 12
        > (define-syntax-class two
            #:attributes (x y)
            (pattern (x y)))
            > (syntax-parse #'(a b)
            [(~var t two) (syntax->datum #'(t t.x t.y))])
```

, ( $(\mathrm{a}$ b) a b)
> (define-syntax-class (nat-less-than $n$ ) (pattern x:nat \#:when (< (syntax-e \#'x) n)))
> (syntax-parse \#'(1 24345$)$ [((~var small (nat-less-than 4)) ... large:nat ...) (list \#'(small ...) \#'(large ...))])
, (\#<syntax:89:0 (1 2 3) > \#<syntax:89:0 (4 5)>)
> (syntax-parse \#' (m a b 3)
[(_ (~var x id \#:role "variable") ...) 'ok])
$m$ : expected identifier for variable at: 3

```
(~literal literal-id maybe-phase)
maybe-phase =
    | #:phase phase-expr
```

A literal identifier pattern. Matches any identifier free-identifier=? to literal-id.
Examples:

```
> (syntax-parse #'(define x 12)
    [((~literal define) var:id body:expr) 'ok])
'ok
> (syntax-parse #'(lambda x 12)
    [((~literal define) var:id body:expr) 'ok])
lambda: expected the identifier 'define' at: lambda
```

The identifiers are compared at the phase given by phase-expr, if it is given, or (syntax-local-phase-level) otherwise.
atomic-datum
Numbers, strings, booleans, keywords, and the empty list match as literals.
Examples:

```
> (syntax-parse #'(a #:foo bar)
    [(x #:foo y) (syntax->datum #'y)])
'bar
> (syntax-parse #'(a foo bar)
                    [(x #:foo y) (syntax->datum #'y)])
a: expected the literal #:foo at: foo
|(~datum datum)
```

Matches syntax whose S-expression contents (obtained by syntax->datum) is equal? to the given datum.

## Examples:

```
> (syntax-parse #'(a #:foo bar)
    [(x (~datum #:foo) y) (syntax->datum #'y)])
'bar
> (syntax-parse #'(a foo bar)
    [(x (~datum #:foo) y) (syntax->datum #'y)])
a: expected the literal #:foo at: foo
```

The $\sim$ datum form is useful for recognizing identifiers symbolically, in contrast to the $\sim l i t e r a l$ form, which recognizes them by binding.
Examples:

```
    > (syntax-parse (let ([define 'something-
    else]) \#'(define x y))
    [((~datum define) var:id e:expr) 'yes]
    [_ 'no])
    'yes
    > (syntax-parse (let ([define 'something-
    else]) \#'(define x y))
    [((~literal define) var:id e:expr) 'yes]
    [_ 'no])
    'no
| (H-pattern . S-pattern)
```

Matches any term that can be decomposed into a list prefix matching $H-$ pattern and a suffix matching $S$-pattern.
Note that the pattern may match terms that are not even improper lists; if the head pattern can match a zero-length head, then the whole pattern matches whatever the tail pattern accepts.
The first pattern can be a single-term pattern, in which case the whole pattern matches any pair whose first element matches the first pattern and whose rest matches the second.
See head patterns for more information.
(A-pattern . S-pattern)
Performs the actions specified by A-pattern, then matches any term that matches S-pattern.
Pragmatically, one can throw an action pattern into any list pattern. Thus, ( $x$ $y z$ ) is a pattern matching a list of three terms, and ( $x$ y $\sim!z$ ) is a pattern matching a list of three terms, with a cut performed after the second one. In other words, action patterns "don't take up space."
See action patterns for more information.

```
(EH-pattern ... . S-pattern)
```

Matches any term that can be decomposed into a list head matching some number of repetitions of the EH-pattern alternatives (subject to its repetition constraints) followed by a list tail matching $S$-pattern.
In other words, the whole pattern matches either the second pattern (which need not be a list) or a term whose head matches one of the alternatives of the first pattern and whose tail recursively matches the whole sequence pattern.
See ellipsis-head patterns for more information.
| (H-pattern ...+ . S-pattern)
Like an ellipses (. . .) pattern, but requires at least one occurrence of the head pattern to be present.
That is, the following patterns are equivalent:

- ( H . . . + . S)
- (( $\sim$ between H 1 +inf.0) ... . S)

Examples:

```
> (syntax-parse #'(1 2 3)
    [(n:nat ...+) 'ok])
,ok
> (syntax-parse #'()
            [(n:nat ...+) ,ok]
            [_ 'none])
'none
```

(~and S/A-pattern ...)

Matches any term that matches all of the subpatterns.
The subpatterns can contain a mixture of single-term patterns and action patterns, but must contain at least one single-term pattern.
Attributes bound in subpatterns are available to subsequent subpatterns. The whole pattern binds all of the subpatterns' attributes.
One use for $\sim$ and-patterns is preserving a whole term (including its lexical context, source location, etc) while also examining its structure. Syntax classes are useful for the same purpose, but $\sim$ and can be lighter weight.
Examples:

```
        > (define-syntax (import stx)
        (raise-syntax-error #f "illegal use of import" stx))
    > (define (check-imports stx) ....)
    > (syntax-parse #'(m (import one two))
        #:literals (import)
        [(_ (~and import-clause (import i ...)))
            (let ([bad (check-imports
                                    (syntax->list #'(i ...)))])
                (when bad
                    (raise-syntax-error
                    #f "bad import" #'import-clause bad))
                ,ok)])
    'ok
|(~or S-pattern ...)
```

Matches any term that matches one of the included patterns. The alternatives are tried in order.
The whole pattern binds all of the subpatterns' attributes. An attribute that is not bound by the "chosen" subpattern has a value of \#f. The same attribute may be bound by multiple subpatterns, and if it is bound by all of the subpatterns, it is sure to have a value if the whole pattern matches.
Examples:

```
> (syntax-parse #'a
            [(~or x:id y:nat) (values (attribute x) (attribute y))])
        #<syntax:104:0 a>
        #f
        > (syntax-parse #'(a 1)
            [(~or (x:id y:nat) (x:id)) (values #'x (attribute y))])
        #<syntax:105:0 a>
        #<syntax:105:0 1>
        > (syntax-parse #'(b)
            [(~or (x:id y:nat) (x:id)) (values #'x (attribute y))])
        #<syntax:106:0 b>
        #f
```

(~not S-pattern)

Matches any term that does not match the subpattern. None of the subpattern's attributes are bound outside of the $\sim$ not-pattern.

Example:

```
    > (syntax-parse #'(x y z => u v)
            #:literals (=>)
            [((~and before (~not =>)) ... => after ...)
            (list #'(before ...) #'(after ...))])
            ,(#<syntax:107:0 (x y z)> #<syntax:107:0 (u v)>)
|#(pattern-part ...)
Matches a term that is a vector whose elements, when considered as a list, match the single-term pattern corresponding to (pattern-part . . .).
Examples:
```

```
> (syntax-parse #'#(1 2 3)
```

> (syntax-parse \#'\#(1 2 3)
[\#(x y z) (syntax->datum \#'z)])
[\#(x y z) (syntax->datum \#'z)])
3
3
> (syntax-parse \#'\#(1 2 3)
> (syntax-parse \#'\#(1 2 3)
[\#(x y ...) (syntax->datum \#'(y ...))])
[\#(x y ...) (syntax->datum \#'(y ...))])
,(2 3)
,(2 3)
> (syntax-parse \#'\#(1 2 3)
> (syntax-parse \#'\#(1 2 3)
[\#(x ~rest y) (syntax->datum \#'y)])
[\#(x ~rest y) (syntax->datum \#'y)])
,}(2 3
,}(2 3
|\#s(prefab-struct-key pattern-part ...)
Matches a term that is a prefab struct whose key is exactly the given key and whose sequence of fields, when considered as a list, match the single-term pattern corresponding to (pattern-part ...).
Examples:

```
```

> (syntax-parse \#'\#s(point 1 2 3)

```
> (syntax-parse #'#s(point 1 2 3)
    [#s(point x y z) 'ok])
    [#s(point x y z) 'ok])
        ,ok
        ,ok
        > (syntax-parse #'#s(point 1 2 3)
        > (syntax-parse #'#s(point 1 2 3)
            [#s(point x y ...) (syntax->datum #'(y ...))])
            [#s(point x y ...) (syntax->datum #'(y ...))])
        ,(2 3)
        ,(2 3)
        > (syntax-parse #'#s(point 1 2 3)
        > (syntax-parse #'#s(point 1 2 3)
            [#s(point x ~rest y) (syntax->datum #'y)])
            [#s(point x ~rest y) (syntax->datum #'y)])
        ,(2 3)
        ,(2 3)
#&S-pattern
```

Matches a term that is a box whose contents matches the inner single-term pattern.

Example:
> (syntax-parse \#'\#\&5
[\#\&n:nat ,ok])
, ok

```
(~rest S-pattern)
```

Matches just like $S$-pattern. The $\sim$ rest pattern form is useful in positions where improper ("dotted") lists are not allowed by the reader, such as vector and structure patterns (see above).
Examples:

```
> (syntax-parse #'(1 2 3)
    [(x ~rest y) (syntax->datum #'y)])
,(2 3)
> (syntax-parse #'#(1 2 3)
            [#(x ~rest y) (syntax->datum #'y)])
,(2 3)
```

```
(~describe maybe-opaque expr S-pattern)
maybe-opaque =
        #:opaque
    maybe-role =
        #:role role-expr
    expr : (or/c string? #f)
    role-expr : (or/c string? #f)
```

The $\sim$ describe pattern form annotates a pattern with a description, a string expression that is evaluated in the scope of all prior attribute bindings. If parsing the inner pattern fails, then the description is used to synthesize the error message. A ~describe pattern does not influence backtracking.
If \#: opaque is given, failure information from within $S$-pattern is discarded and the error is reported solely in terms of the description given.
If role-expr is given and produces a string, its value is combined with the description in error messages.
Examples:

```
> (syntax-parse #'(m 1)
```

            [(_ (~describe "id pair" (x:id y:id))) 'ok])
    m: expected id pair at: 1

```
> (syntax-parse #'(m (a 2))
            [(_ (~describe "id pair" (x:id y:id))) 'ok])
m: expected identifier
    parsing context:
                while parsing id pair at: 2
> (syntax-parse #'(m (a 2))
            [(_ (~describe #:opaque "id pair" (x:id y:id))) 'ok])
m: expected id pair at: (a 2)
> (syntax-parse #'(m 1)
            [(_ (~describe #:role "formals" "id
pair" (x y))) 'ok])
m: expected id pair for formals at: 1
```

\| (~commit S-pattern)

The $\sim$ commit pattern form affects backtracking in two ways:

- If the pattern succeeds, then all choice points created within the subpattern are discarded, and a failure after the $\sim$ commit pattern backtracks only to choice points before the $\sim$ commit pattern, never one within it.
- A cut ( $\sim$ ) ) within a $\sim$ commit pattern only eliminates choice-points created within the $\sim$ commit pattern. In this sense, it acts just like $\sim$ delimit-cut.
| ( $\sim$ delimit-cut $S$-pattern)
The $\sim$ delimit-cut pattern form affects backtracking in the following way:
- A cut ( $\sim!$ ) within a $\sim$ delimit-cut pattern only eliminates choice-points created within the $\sim$ delimit-cut pattern.
| A-pattern
An action pattern is considered a single-term pattern when there is no ambiguity; it matches any term.

### 1.5.2 Head Patterns

A head pattern (abbreviated H-pattern) is a pattern that describes some number of terms that occur at the head of some list (possibly an improper list). A head pattern's usefulness comes from being able to match heads of different lengths, such as optional forms like keyword arguments.

A proper head pattern is a head pattern that is not a single-term pattern.
Here are the variants of head pattern:

```
|pvar-id:splicing-syntax-class-id
```

Equivalent to ( $\sim$ var pvar-id splicing-syntax-class-id).

```
(~var pvar-id splicing-syntax-class-use maybe-role)
splicing-syntax-class-use = splicing-syntax-class-id
    | (splicing-syntax-class-id arg ...)
        maybe-role =
    | #:role role-expr
    role-expr : (or/c string? #f)
```

Pattern variable annotated with a splicing syntax class. Similar to a normal annotated pattern variable, except matches a head pattern.
| (~seq . L-pattern)

Matches a sequence of terms whose elements, if put in a list, would match $L$ pattern.
Example:

```
> (syntax-parse #'(1 2 3 4)
    [((~seq 1 2 3) 4) 'ok])
,ok
```

See also the section on ellipsis-head patterns for more interesting examples of $\sim$ seq.
(~and H-pattern ...)

Like the single-term pattern version, $\sim \operatorname{and}^{s}$, but matches a sequence of terms instead.

Example:

```
> (syntax-parse #'(#:a 1 #:b 2 3 4 5)
    [((~and (~seq (~seq k:keyword e:expr) ...)
            (~seq keyword-stuff ...))
        positional-stuff ...)
        (syntax->datum #'((k ...) (e ...) (keyword-
stuff ...)))])
'((#:a #:b) (1 2) (#:a 1 #:b 2))
```

The head pattern variant of $\sim$ and requires that all of the subpatterns be proper head patterns (not single-term patterns). This is to prevent typos like the following, a variant of the previous example with the second $\sim$ seq omitted:
Examples:

```
> (syntax-parse #'(#:a 1 #:b 2 3 4 5)
    [((~and (~seq (~seq k:keyword e:expr) ...)
            (keyword-stuff ...))
        positional-stuff ...)
        (syntax->datum #'((k ...) (e ...) (keyword-
stuff ...)))])
syntax-parse: single-term pattern not allowed after head
pattern at: (keyword-stuff ...)
; If the example above were allowed, it would be equiva-
lent to this:
> (syntax-parse #'(#:a 1 #:b 2 3 4 5)
        [((~and (~seq (~seq k:keyword e:expr) ...)
            (~seq (keyword-stuff ...)))
            positional-stuff ...)
    (syntax->datum #'((k ...) (e ...) (keyword-
stuff ...)))])
?: expected keyword at: 3
```

(~or H-pattern ...)

Like the single-term pattern version, $\sim \mathrm{or}^{\mathrm{s}}$, but matches a sequence of terms instead.
Examples:

```
> (syntax-parse #'(m #:foo 2 a b c)
    [(_ (~or (~seq #:foo x) (~seq)) y:id ...)
            (attribute x)])
#<syntax:125:0 2>
> (syntax-parse #'(m a b c)
    [(_ (~or (~seq #:foo x) (~seq)) y:id ...)
            (attribute x)])
#f
```

```
(~optional H-pattern maybe-optional-option)
maybe-optional-option =
    | #:defaults ([attr-arity-decl expr] ...)
    attr-arity-decl = attr-id
    | (attr-id depth)
```

Matches either the given head subpattern or an empty sequence of terms. If the \#:defaults option is given, the subsequent attribute bindings are used if the subpattern does not match. The default attributes must be a subset of the subpattern's attributes.
Examples:

```
> (syntax-parse #'(m #:foo 2 a b c)
    [(_ (~optional (~seq #:foo x) #:defaults ([x #'#f])) y:id ...)
        (attribute x)])
#<syntax:127:0 2>
> (syntax-parse #'(m a b c)
    [(_ (~optional (~seq #:foo x) #:defaults ([x #'#f])) y:id ...)
        (attribute x)])
#<syntax:128:0 #f>
> (syntax-parse #'(m a b c)
            [(_ (~optional (~seq #:foo x)) y:id ...)
            (attribute x)])
#f
> (syntax-parse #'(m #:syms a b c)
            [(_ (~optional (~seq #:nums n:nat ...) #:defaults ([(n 1) null]))
                    (~optional (~seq #:syms s:id ...) #:defaults ([(s 1) null])))
            #'((n ...) (s ...))])
#<syntax:130:0 (() (a b c))>
|(~describe expr H-pattern)
```

Like the single-term pattern version, $\sim$ describe ${ }^{s}$, but matches a head pattern instead.

```
|(~commit H-pattern)
```

Like the single-term pattern version, $\sim$ commit $^{\text {s }}$, but matches a head pattern instead.

```
(~delimit-cut H-pattern)
```

Like the single-term pattern version, $\sim$ delimit-cut ${ }^{\text {s }}$, but matches a head pattern instead.

```
| (~peek H-pattern)
```

Matches the $H$-pattern but then resets the matching position, so the $\sim$ peek pattern consumes no input. Used to look ahead in a sequence.
Examples:

```
> (define-splicing-syntax-class nf-id ; non-final id
    (pattern (~seq x:id (~ peek another:id))))
> (syntax-parse #'(a b c 1 2 3)
            [(n:nf-id ... rest ...)
                    (printf "nf-ids are ~s\n" (syntax-
>datum #'(n.x ...)))
            (printf "rest is ~s\n" (syntax-
>datum #'(rest ...)))])
nf-ids are (a b)
rest is (c 1 2 3)
|(~peek-not H-pattern)
```

Like $\sim$ peek, but succeeds if the subpattern fails and fails if the subpattern succeeds. On success, the $\sim$ peek-not resets the matching position, so the pattern consumes no input. Used to look ahead in a sequence. None of the subpattern's attributes are bound outside of the $\sim$ peek-not-pattern.
Examples:

```
> (define-splicing-syntax-class final ; final term
    (pattern (~seq x (~peek-not _))))
> (syntax-parse #'(a b c)
    [((~or f:final other) ...)
            (printf "finals are ~s\n" (syntax-
>datum #'(f.x ...)))
            (printf "others are ~s\n" (syntax-
>datum #'(other ...)))])
finals are (c)
others are (a b)
```

| S-pattern

Matches a sequence of one element, which must be a term matching $S$ pattern.

### 1.5.3 Ellipsis-head Patterns

An ellipsis-head pattern (abbreviated EH-pattern) is pattern that describes some number of terms, like a head pattern, but also places constraints on the number of times it occurs in a repetition. They are useful for matching, for example, keyword arguments where the keywords may come in any order. Multiple alternatives are grouped together via $\sim \mathrm{or}^{\mathrm{eh}}$.

## Examples:

```
> (define parser1
    (syntax-parser
        [((~or (~once (~seq #:a x) #:name "#:a keyword")
                                (~optional (~seq #:b y) #:name "#:b keyword")
                                (~seq #:c z)) ...)
            'ok]))
> (parser1 #'(#:a 1))
'ok
> (parser1 #'(#:b 2 #:c 3 #:c 25 #:a 'hi))
'ok
> (parser1 #'(#:a 1 #:a 2))
?: too many occurrences of #:a keyword at:(#:a 1 #:a 2)
```

The pattern requires exactly one occurrence of the \#: a keyword and argument, at most one occurrence of the \#:b keyword and argument, and any number of \#:c keywords and arguments. The "pieces" can occur in any order.

Here are the variants of ellipsis-head pattern:
\| (~or EH-pattern ...)
Matches if any of the inner EH-pattern alternatives match.

```
(~once H-pattern once-option ...)
once-option = #:name name-expr
    | #:too-few too-few-message-expr
    | #:too-many too-many-message-expr
    name-expr : (or/c string? #f)
    too-few-message-expr : (or/c string? #f)
    too-many-message-expr : (or/c string? #f)
```

Matches if the inner H-pattern matches. This pattern must be matched exactly once in the match of the entire repetition sequence.

If the pattern is not matched in the repetition sequence, then the ellipsis pattern fails with the message either too-few-message-expr or "missing required occurrence of name-expr".
If the pattern is chosen more than once in the repetition sequence, then the ellipsis pattern fails with the message either too-many-message-expr or "too many occurrences of name-expr".

```
(~optional H-pattern optional-option ...)
optional-option = #:name name-expr
    | #:too-many too-many-message-expr
    | #:defaults ([attr-id expr] ...)
    name-expr : (or/c string? #f)
    too-many-message-expr : (or/c string? #f)
```

Matches if the inner H-pattern matches. This pattern may be used at most once in the match of the entire repetition.
If the pattern is matched more than once in the repetition sequence, then the ellipsis pattern fails with the message either too-many-message-expr or "too many occurrences of name-expr".
If the \#: defaults option is given, the following attribute bindings are used if the subpattern does not match at all in the sequence. The default attributes must be a subset of the subpattern's attributes.

```
(~between H-pattern min-number max-number between-option ...)
reps-option = #:name name-expr
    | #:too-few too-few-message-expr
    | #:too-many too-many-message-expr
    name-expr : (or/c syntax? #f)
    too-few-message-expr : (or/c syntax? #f)
```

Matches if the inner $H$-pattern matches. This pattern must be matched at least min-number and at most max-number times in the entire repetition.
If the pattern is matched too few times, then the ellipsis pattern fails with the message either too-few-message-expr or "too few occurrences of name-expr".
If the pattern is chosen too many times, then the ellipsis pattern fails with the message either too-many-message-expr or "too few occurrences of name-expr".

### 1.5.4 Action Patterns

An action pattern (abbreviated A-pattern) does not describe any syntax; rather, it has an effect such as the binding of attributes or the modification of the matching process.
\|!

The cut operator, written $\sim!$, eliminates backtracking choice points and commits parsing to the current branch of the pattern it is exploring.
Common opportunities for cut-patterns come from recognizing special forms based on keywords. Consider the following expression:

```
> (syntax-parse #'(define-values a 123)
    #:literals (define-values define-syntaxes)
    [(define-values (x:id ...) e) 'define-values]
    [(define-syntaxes (x:id ...) e) 'define-syntaxes]
    [e 'expression])
'expression
```

Given the ill-formed term (define-values a 123), syntax-parse tries the first clause, fails to match a against the pattern ( $\mathrm{x}:$ id ...), and then backtracks to the second clause and ultimately the third clause, producing the value ' expression. But the term is not an expression; it is an ill-formed use of define-values. The proper way to write the syntax-parse expression follows:

```
> (syntax-parse #'(define-values a 123)
    #:literals (define-values define-syntaxes)
    [(define-values ~! (x:id ...) e) 'define-values]
    [(define-syntaxes ~! (x:id ...) e) 'define-syntaxes]
    [e 'expression])
define-values: bad syntax at: (define-values a 123)
```

Now, given the same term, syntax-parse tries the first clause, and since the keyword define-values matches, the cut-pattern commits to the current pattern, eliminating the choice points for the second and third clauses. So when the clause fails to match, the syntax-parse expression raises an error.

The effect of a $\sim$ ! pattern is delimited by the nearest enclosing $\sim$ delimitcut or $\sim$ commit pattern. If there is no enclosing $\sim$ describe pattern but the cut occurs within a syntax class definition, then only choice points within the syntax class definition are discarded. A $\sim!$ pattern is not allowed within a $\sim$ not pattern unless there is an intervening $\sim$ delimit-cut or $\sim$ commit pattern.

```
(~bind [attr-arity-decl expr] ...)
attr-arity-decl = attr-name-id
    | (attr-name-id depth)
```

Evaluates the exprs and binds them to the given attr-ids as attributes.

```
(~fail maybe-fail-condition maybe-message-expr)
maybe-fail-condition =
    | #:when condition-expr
    | #:unless condition-expr
    maybe-message-expr =
    | message-expr
    message-expr : (or/c string? #f)
```

If the condition is absent, or if the \#: when condition evaluates to a true value, or if the \#: unless condition evaluates to \#f, then the pattern fails with the given message. If the message is omitted, the default value $\# \mathrm{f}$ is used, representing "no message."

Fail patterns can be used together with cut patterns to recognize specific illformed terms and address them with custom failure messages.
| (~parse S-pattern stx-expr)
Evaluates stx-expr and matches it against $S$-pattern. If stx-expr does not produce a syntax object, the value is implicitly converted to a syntax object, unless the conversion would produce 3D syntax, in which case an exception is raised instead.
| (~and A-pattern ...+)
Performs the actions of each A-pattern.
\|( $\sim$ do defn-or-expr ...)
Takes a sequence of definitions and expressions, which may be intermixed, and evaluates them in the scope of all previous attribute bindings. The names bound
by the definitions are in scope in the expressions of subsequent patterns and clauses.
There is currently no way to bind attributes using a $\sim$ do pattern. It is an error to shadow an attribute binding with a definition in a $\sim$ do block.
Example:

```
> (syntax-parse #'(1 2 3)
    [(a b (~do (printf "a was ~s\n" #'a)) c:id) 'ok])
a was #<syntax:141:0 1>
?: expected identifier at: }
```

### 1.6 Defining Simple Macros

```
(require syntax/parse/define) package: base
(define-simple-macro (macro-id . pattern) pattern-directive ...
    template)
```

Defines a macro named macro-id; equivalent to the following:

```
(define-syntax (macro-id stx)
    (syntax-parse stx
            [(macro-id . pattern) pattern-directive ... #'template]))
```

Examples:

```
> (define-simple-macro (fn x:id rhs:expr) (lambda (x) rhs))
>((fn x x) 17)
1 7
>(fn 1 2)
fn: expected identifier at: 1
> (define-simple-macro (fn2 x y rhs)
        #:declare x id
        #:declare y id
        #:declare rhs expr
        (lambda (x y) rhs))
> ((fn2 a b (+ a b)) 3 4)
7
> (fn2 a #:b 'c)
fn2: expected identifier at: #:b
```

### 1.7 Literal Sets and Conventions

Sometimes the same literals are recognized in a number of different places. The most common example is the literals for fully expanded programs, which are used in many analysis
and transformation tools. Specifying literals individually is burdensome and error-prone. As a remedy, syntax/parse offers literal sets. A literal set is defined via define-literalset and used via the \#:literal-set option of syntax-parse.

```
(define-literal-set id maybe-phase maybe-imports maybe-datum-literals
    (literal ...))
                    literal = literal-id
                            | (pattern-id literal-id)
                maybe-phase =
                            | \#:for-template
                            | \#:for-syntax
                            | \#:for-label
                            | \#:phase phase-level
maybe-datum-literals =
                            | \#:datum-literals (datum-literal ...)
        maybe-imports =
                        | \#:literal-sets (imported-litset-id ...)
```

Defines id as a literal set. Each literal can have a separate pattern-id and literalid. The pattern-id determines what identifiers in the pattern are treated as literals. The literal-id determines what identifiers the literal matches. If the \#:literal-sets option is present, the contents of the given imported-litset-ids are included.

## Examples:

```
> (define-literal-set def-litset
    (define-values define-syntaxes))
> (syntax-parse #'(define-syntaxes (x) 12)
    #:literal-sets (def-litset)
    [(define-values (x:id ...) e:expr) 'v]
    [(define-syntaxes (x:id ...) e:expr) 's])
's
```

The literals in a literal set always refer to the bindings at phase phase-level relative to the enclosing module. If the \#:for-template option is given, phase-level is -1; \#:forsyntax means 1, and \#:for-label means \#f. If no phase keyword option is given, then phase-level is 0 .

For example:

## Examples:

> (module common racket/base

```
    (define x 'something)
    (provide x))
> (module lits racket/base
    (require syntax/parse 'common)
    (define-literal-set common-lits (x))
    (provide common-lits))
```

In the literal set common-lits, the literal x always recognizes identifiers bound to the variable x defined in module ' common.

The following module defines an equivalent literal set, but imports the 'common module for-template instead:

## Example:

```
> (module lits racket/base
    (require syntax/parse (for-template 'common))
    (define-literal-set common-lits #:for-template (x))
    (provide common-lits))
```

When a literal set is used with the \#: phase phase-expr option, the literals' fixed bindings are compared against the binding of the input literal at the specified phase. Continuing the example:

Examples:

```
> (require syntax/parse 'lits (for-syntax 'common))
> (syntax-parse #'x #:literal-sets ([common-lits #:phase 1])
    [x 'yes]
    [_ 'no])
'yes
```

The occurrence of $x$ in the pattern matches any identifier whose binding at phase 1 is the $x$ from module ' common.

```
(literal-set->predicate litset-id)
```

Given the name of a literal set, produces a predicate that recognizes identifiers in the literal set. The predicate takes one required argument, an identifier id, and one optional argument, the phase phase at which to examine the binding of id; the phase argument defaults to (syntax-local-phase-level).

Examples:

```
> (define kernel? (literal-set->predicate kernel-literals))
> (kernel? #'lambda)
#f
> (kernel? #'#%plain-lambda)
```

```
#t
> (kernel? #'define-values)
#t
> (kernel? #'define-values 4)
#f
(define-conventions name-id convention-rule ...)
convention-rule = (name-pattern syntax-class)
    name-pattern = exact-id
    | name-rx
    syntax-class = syntax-class-id
    | (syntax-class-id expr ...)
```

Defines conventions that supply default syntax classes for pattern variables. A pattern variable that has no explicit syntax class is checked against each name-pattern, and the first one that matches determines the syntax class for the pattern. If no name-pattern matches, then the pattern variable has no syntax class.

Examples:

```
> (define-conventions xyz-as-ids
    [x id] [y id] [z id])
> (syntax-parse #'(a b c 1 2 3)
    #:conventions (xyz-as-ids)
    [(x ... n ...) (syntax->datum #'(x ...))])
,(a b c)
> (define-conventions xn-prefixes
    [#rx"^x" id]
    [#rx"^n" nat])
> (syntax-parse #'(a b c 1 2 3)
    #:conventions (xn-prefixes)
    [(x0 x ... n0 n ...)
        (syntax->datum #'(x0 (x ...) n0 (n ...)))])
,(a (b c) 1 (2 3))
```

Local conventions, introduced with the \#:local-conventions keyword argument of syntax-parse and syntax class definitions, may refer to local bindings:

Examples:

```
> (define-syntax-class (nat> bound)
    (pattern n:nat
        #:fail-unless (> (syntax-e #'n) bound)
                            (format "expected number >
~s" bound)))
```

```
> (define-syntax-class (natlist> bound)
    #:local-conventions ([N (nat> bound)])
    (pattern (N ...)))
> (define (parse-natlist> bound x)
    (syntax-parse x
        #:local-conventions ([NS (natlist> bound)])
        [NS ,ok]))
> (parse-natlist> 0 #'(1 2 3))
    ,ok

### 1.8 Library Syntax Classes and Literal Sets

### 1.8.1 Syntax Classes

| expr

Matches anything except a keyword literal (to distinguish expressions from the start of a keyword argument sequence). The term is not otherwise inspected, since it is not feasible to check if it is actually a valid expression.

```
identifier
boolean
str
char
keyword
number
integer
exact-integer
exact-nonnegative-integer
exact-positive-integer
```

Match syntax satisfying the corresponding predicates.
id

Alias for identifier.
\|nat

Alias for exact-nonnegative-integer.

```
(static predicate description) }->\mathrm{ (attributes value)
    predicate : (-> any/c any/c)
    description : (or/c string? #f)
```

The static syntax class matches an identifier that is bound in the syntactic environment to static information (see syntax-local-value) satisfying the given predicate. If the term does not match, the description argument is used to describe the expected syntax.

When used outside of the dynamic extent of a macro transformer (see syntaxtransforming?), matching fails.

The attribute value contains the value the name is bound to.

```
expr/c contract-expr
    [\#:positive pos-blame
    \#:negative neg-blame
    \#:name expr-name
    \#:macro macro-name
    \#:context ctx]) \(\quad \rightarrow\) (attributes c)
    contract-expr : syntax?
    pos-blame : (or/c syntax? string? module-path-index? 'from-macro 'use-site 'unknown)
        = 'use-site
    neg-blame : (or/c syntax? string? module-path-index? 'from-macro 'use-site 'unknown)
        \(=\) 'from-macro
    expr-name : (or/c identifier? string? symbol?) \(=\# f\)
    macro-name : (or/c identifier? string? symbol?) = \#f
    ctx : (or/c syntax? \#f) = determined automatically
```

Accepts an expression (expr) and computes an attribute $c$ that represents the expression wrapped with the contract represented by contract-expr.

The contract's positive blame represents the obligations of the expression being wrapped. The negative blame represents the obligations of the macro imposing the contract-the ultimate user of expr/c. By default, the positive blame is taken as the module currently being expanded, and the negative blame is inferred from the definition site of the macro (itself inferred from the context argument), but both blame locations can be overridden.

The pos-blame and neg-blame arguments are turned into blame locations as follows:

- If the argument is a string, it is used directly as the blame label.
- If the argument is syntax, its source location is used to produce the blame label.
- If the argument is a module path index, its resolved module path is used.
- If the argument is 'from-macro, the macro is inferred from either the macro-name argument (if macro-name is an identifier) or the context argument, and the module where it is defined is used as the blame location. If neither an identifier macro-name nor a context argument is given, the location is "unknown".
- If the argument is'use-site, the module being expanded is used.
- If the argument is 'unknown, the blame label is "unknown".

The macro-name argument is used to determine the macro's binding, if it is an identifier. If expr-name is given, macro-name is also included in the contract error message. If macroname is omitted or \#f, but context is a syntax object, then macro-name is determined from context.

If expr-name is not $\# f$, it is used in the contract's error message to describe the expression the contract is applied to.

The context argument is used, when necessary, to infer the macro name for the negative blame party and the contract error message. The context should be either an identifier or a syntax pair with an identifier in operator position; in either case, that identifier is taken as the macro ultimately requesting the contract wrapping.

See 1.2.6 "Contracts on Macro Sub-expressions" for an example.
Important: Make sure when using expr/c to use the c attribute. The expr/c syntax class does not change how pattern variables are bound; it only computes an attribute that represents the checked expression.

### 1.8.2 Literal Sets

|kernel-literals

Literal set containing the identifiers for fully-expanded code (§1.2.3.1 "Fully Expanded Programs"). The set contains all of the forms listed by kernel-form-identifier-list, plus module, \#\%plain-module-begin, \#\%require, and \#\%provide.

Note that the literal-set uses the names \#\%plain-lambda and \#\%plain-app, not lambda and \#\%app.

### 1.9 Debugging and Inspection Tools

```
(require syntax/parse/debug) package: base
```

The following special forms are for debugging syntax classes.

```
|(syntax-class-attributes syntax-class-id)
```

Returns a list of the syntax class's attributes. Each attribute entry consists of the attribute's name and ellipsis depth.

```
(syntax-class-arity syntax-class-id)
(syntax-class-keywords syntax-class-id)
```

Returns the syntax class's arity and keywords, respectively. Compare with procedurearity and procedure-keywords.

```
(syntax-class-parse syntax-class-id stx-expr arg ...)
    stx-expr : syntax?
```

Runs the parser for the syntax class (parameterized by the arg-exprs) on the syntax object produced by stx-expr. On success, the result is a list of vectors representing the attribute bindings of the syntax class. Each vector contains the attribute name, depth, and associated value. On failure, the result is some internal representation of the failure.

```
(debug-parse stx-expr S-pattern ...+)
    stx-expr : syntax?
```

Tries to match stx-expr against the $S$-patterns. If matching succeeds, the symbol 'success is returned. Otherwise, an S-expression describing the failure is returned.

The failure S-expression shows both the raw set of failures (unsorted) and the failures with maximal progress. The maximal failures are divided into equivalence classes based on their progress (progress is a partial order); that is, failures within an equivalence class have the same progress and, in principle, pinpoint the same term as the problematic term. Multiple equivalence classes only arise from $\sim$ parse patterns (or equivalently, \#:with clauses) that match computed terms or $\sim$ fail (\#:fail-when, etc) clauses that allow a computed term to be pinpointed.

### 1.10 Experimental

The following facilities are experimental.

### 1.10.1 Contracts for Macro Sub-expressions

```
(require syntax/parse/experimental/contract)
```

package: base
This module is deprecated; it reprovides expr/c for backward compatibility.

### 1.10.2 Contracts for Syntax Classes

```
    (require syntax/parse/experimental/provide)
        package: base
(provide-syntax-class/contract
    [syntax-class-id syntax-class-contract] ...)
syntax-class-contract = (syntax-class/c (mandatory-arg ...))
            | (syntax-class/c (mandatory-arg ...)
                                    (optional-arg ...))
            arg = contract-expr
                        | keyword contract-expr
    contract-expr : contract?
```

Provides the syntax class (or splicing syntax class) syntax-class-id with the given contracts imposed on its formal parameters.
syntax-class/c

Keyword recognized by provide-syntax-class/contract.

### 1.10.3 Reflection

(require syntax/parse/experimental/reflect) package: base

A syntax class can be reified into a run-time value, and a reified syntax class can be used in a pattern via the $\sim$ reflect and $\sim$ splicing-reflect pattern forms.

```
|(reify-syntax-class syntax-class-id)
```

Reifies the syntax class named syntax-class-id as a run-time value. The same form also handles splicing syntax classes. Syntax classes with the \#:no-delimit-cut option cannot be reified.

```
(reified-syntax-class? x) -> boolean?
    x : any/c
(reified-splicing-syntax-class? x) -> boolean?
    x : any/c
```

Returns \#t if $x$ is a reified (normal) syntax class or a reified splicing syntax class, respectively.

```
(reified-syntax-class-attributes r)
->(listof (list/c symbol? exact-nonnegative-integer?))
    r : (or/c reified-syntax-class? reified-splicing-syntax-class?)
```

Returns the reified syntax class's attributes.

```
(reified-syntax-class-arity r) }->\mathrm{ procedure-arity?
    r : (or/c reified-syntax-class? reified-splicing-syntax-class?)
(reified-syntax-class-keywords r)
    (listof keyword?) (listof keyword?)
    r : (or/c reified-syntax-class? reified-splicing-syntax-class?)
```

Returns the reified syntax class's arity and keywords, respectively. Compare with procedure-arity and procedure-keywords.

```
(reified-syntax-class-curry r
    arg ...
    #:<kw> kw-arg ...)
    ->(or/c reified-syntax-class? reified-splicing-syntax-class?)
    r : (or/c reified-syntax-class? reified-splicing-syntax-class?)
    arg : any/c
    kw-arg : any/c
```

Partially applies the reified syntax class to the given arguments. If more arguments are given than the reified syntax class accepts, an error is raised.

```
S-pattern = ...
    | (~reflect var-id (reified-expr arg-expr ...) maybe-attrs)
    H-pattern = ....
    | (~splicing-reflect var-id (reified-expr arg-expr ...)
    maybe-attrs)
(~reflect var-id (reified-expr arg-expr ...) maybe-attrs)
```

```
maybe-attrs =
    | #:attributes (attr-arity-decl ...)
```

Like $\sim$ var, except that the syntax class position is an expression evaluating to a reified syntax object, not a syntax class name, and the attributes bound by the reified syntax class (if any) must be specified explicitly.

```
|(~splicing-reflect var-id (reified-expr arg-expr ...) maybe-attrs)
```

Like $\sim r e f l e c t ~ b u t ~ f o r ~ r e i f i e d ~ s p l i c i n g ~ s y n t a x ~ c l a s s e s . ~$

## Examples:

```
> (define-syntax-class (nat> x)
    #:description (format "natural number greater than ~s" x)
    #:attributes (diff)
    (pattern n:nat
            #:when (> (syntax-e #'n) x)
            #:with diff (- (syntax-e #'n) x)))
> (define-syntax-class (nat/mult x)
    #:description (format "natural number multiple of ~s" x)
    #:attributes (quot)
    (pattern n:nat
                        #:when (zero? (remainder (syntax-e #'n) x))
                            #:with quot (quotient (syntax-e #'n) x)))
> (define r-nat> (reify-syntax-class nat>))
> (define r-nat/mult (reify-syntax-class nat/mult))
> (define (partition/r stx r n)
    (syntax-parse stx
            [((~or (~reflect yes (r n)) no) ...)
            #'((yes ...) (no ...))]))
> (partition/r #'(1 2 3 4 5) r-nat> 3)
#<syntax:174:0 ((4 5) (1 2 3))>
> (partition/r #'(1 2 3 4 5) r-nat/mult 2)
#<syntax:174:0 ((2 4) (1 3 5))>
> (define (bad-attrs r)
    (syntax-parse #'6
        [(~reflect x (r 3) #:attributes (diff))
            #'x.diff]))
> (bad-attrs r-nat>)
#<syntax 3>
> (bad-attrs r-nat/mult)
reflect-syntax-class: reified syntax-class is missing
declared attribute 'diff'
```

### 1.10.4 Procedural Splicing Syntax Classes

```
(require syntax/parse/experimental/splicing)
        package: base
(define-primitive-splicing-syntax-class (name-id param-id ...)
    maybe-description maybe-attrs
    parser-expr)
        (-> syntax?
    parser : (->* () ((or/c string? #f) -> any))
    (cons/c exact-positive-integer? list?))
```

Defines a splicing syntax via a procedural parser.
The parser procedure is given two arguments, the syntax to parse and a failure procedure. To signal a successful parse, the parser procedure returns a list of $N+1$ elements, where $N$ is the number of attributes declared by the splicing syntax class. The first element is the size of the prefix consumed. The rest of the list contains the values of the attributes.

To indicate failure, the parser calls the failure procedure with an optional message argument.

### 1.10.5 Ellipsis-head Alternative Sets

```
(require syntax/parse/experimental/eh) package: base
```

Unlike single-term patterns and head patterns, ellipsis-head patterns cannot be encapsulated by syntax classes, since they describe not only sets of terms but also repetition constraints.

This module provides ellipsis-head alternative sets, reusable encapsulations of ellipsis-head patterns.

```
(define-eh-alternative-set name eh-alternative ...)
alternative = (pattern EH-pattern)
```

Defines name as an ellipsis-head alternative set. Using name (via ~eh-var) in an ellipsishead pattern is equivalent to including each of the alternatives in the pattern via $\sim \mathrm{or}^{\mathrm{eh}}$, except that the attributes bound by the alternatives are prefixed with the name given to $\sim$ ehvar.

Unlike syntax classes, ellipsis-head alternative sets must be defined before they are referenced.

```
EH-pattern = ....
    (~eh-var name eh-alternative-set-id)
```

```
(~eh-var name eh-alternative-set-id)
```

Includes the alternatives of eh-alternative-set-id, prefixing their attributes with name.

Examples:

```
> (define-eh-alternative-set options
    (pattern (~once (~seq #:a a:expr) #:name "#:a option"))
    (pattern (~seq #:b b:expr)))
> (define (parse/options stx)
    (syntax-parse stx
            [(_ (~eh-var s options) ...)
            #'(s.a (s.b ...))]))
> (parse/options #'(m #:a 1 #:b 2 #:b 3))
#<syntax:181:0 (1 (2 3))>
> (parse/options #'(m #:a 1 #:a 2))
m: too many occurrences of #:a option at: (m #:a 1 #:a 2)
> (define (parse/more-options stx)
        (syntax-parse stx
            [(_ (~or (~eh-var s options)
                (~seq #:c c1:expr c2:expr))
                    ...)
            #'(s.a (s.b ...) ((c1 c2) ...))]))
> (parse/more-options #'(m #:a 1 #:b 2 #:c 3 4 #:c 5 6))
#<syntax:184:0 (1 (2) ((3 4) (5 6)))>
> (define-eh-alternative-set ext-options
    (pattern (~eh-var s options))
    (pattern (~seq #:c c1 c2)))
> (syntax-parse #'(m #:a 1 #:b 2 #:c 3 4 #:c 5 6)
    [(_ (~eh-var x ext-options) ...)
    #'(x.s.a (x.s.b ...) ((x.c1 x.c2) ...))])
#<syntax:187:0 (1 (2) ((3 4) (5 6)))>
```

### 1.10.6 Syntax Class Specialization

```
    (require syntax/parse/experimental/specialize)
                                    package: base
(define-syntax-class/specialize header syntax-class-use)
    header = id
            | (id . kw-formals)
syntax-class-use = target-stxclass-id
    | (target-stxclass-id arg ...)
```

Defines id as a syntax class with the same attributes, options (eg, \#:commit, \#:no-delimit-cut), and patterns as target-stxclass-id but with the given args supplied.

Examples:

```
> (define-syntax-class/specialize nat>10 (nat> 10))
> (syntax-parse #'(11 12) [(n:nat>10 ...) 'ok])
'ok
> (syntax-parse #'(8 9) [(n:nat>10 ...) ,ok])
?: expected natural number greater than 10 at: 8
```

### 1.10.7 Syntax Templates

```
(require syntax/parse/experimental/template)
                                    package: base
(template tmpl)
    tmpl = pattern-variable-id
        | (head-tmpl . tmpl)
        | (head-tmpl ellipsis ...+ . tmpl)
        | (metafunction-id . tmpl)
        | (?? tmpl tmpl)
        | #(head-tmpl ...)
        | #s(prefab-struct-key head-tmpl ...)
        | #&tmpl
        | constant-term
head-templ = tmpl
    | (?? head-tmpl)
    | (?? head-tmpl head-tmpl)
    | (?@ . tmpl)
    ellipsis = ...
```

Constructs a syntax object from a syntax template, like syntax, but provides additional templating forms for dealing with optional terms and splicing sequences of terms. Only the additional forms are described here; see syntax for descriptions of pattern variables, etc.
| (?? tmpl alt-tmpl)
Produces tmpl unless any attribute used in tmpl has an absent value; in that case, alt-tmpl is used instead.

Examples:

```
> (syntax-parse #'(m 1 2 3)
    [(_ (~optional (~seq #:op op:expr)) arg:expr ...)
        (template ((?? op +) arg ...))])
#<syntax:191:0 (+ 1 2 3)>
> (syntax-parse #'(m #:op max 1 2 3)
    [(_ (~optional (~seq #:op op:expr)) arg:expr ...)
        (template ((?? op +) arg ...))])
#<syntax:192:0 (max 1 2 3)>
```

If ?? is used as a head-template, then its sub-templates may also be headtemplates.

## Examples:

```
> (syntax-parse #'(m 1)
    [(_ x:expr (~optional y:expr))
        (template (m2 x (?? (?@ #:y y) (?@ #:z 0))))])
#<syntax:193:0 (m2 1 #:z 0)>
> (syntax-parse #'(m 1 2)
    [(_ x:expr (~optional y:expr))
        (template (m2 x (?? (?@ #:y y) (?@ #:z 0))))])
#<syntax:194:0 (m2 1 #:y 2)>
```

(?? head-tmpl)
Produces head-tmpl unless any attribute used in head-tmpl has an absent value; in that case, the term is omitted. Can only occur in head position in a template.

Equivalent to (?? head-tmpl (?@)).
Examples:

```
> (syntax-parse #'(m 1)
    [(_ x:expr (~optional y:expr))
        (template (m2 x (?? y)))])
#<syntax:195:0 (m2 1)>
> (syntax-parse #'(m 1 2)
    [(_ x:expr (~optional y:expr))
        (template (m2 x (?? y)))])
#<syntax:196:0 (m2 1 2)>
> (syntax-parse #'(m 1 2)
    [(_ x:expr (~optional y:expr))
        (template (m2 x (?? (?@ #:y y))))])
#<syntax:197:0 (m2 1 #:y 2)>
```

```
(?@ . tmpl)
```

Similar to unquote-splicing, splices the result of tmpl (which must produce a syntax list) into the surrounding template. Can only occur in head position in a template.
Example:

```
> (syntax-parse #'(m #:a 1 #:b 2 3 4 #:e 5)
    [(_ (~or pos:expr (~seq kw:keyword kwarg:expr)) ...)
        (template (m2 (?@ kw kwarg) ... pos ...))])
#<syntax:198:0 (m2 #:a 1 #:b 2 #:e 5 3 4)>
```

The tmpl must produce a proper syntax list, but it does not need to be expressed as a proper list. For example, to unpack pattern variables that contain syntax lists, use a "dotted" template:
Examples:

```
> (with-syntax ([x #'(a b c)])
    (template ((?@ . x) d)))
#<syntax:199:0 (a b c d)>
> (with-syntax ([(x ...) #'((1 2 3) (4 5) )])
    (template ((?@ . x) ...)))
#<syntax:200:0 (1 2 3 4 5)>
```

```
| (metafunction-id . tmpl)
```

Applies the template metafunction named metafunction-id to the result of the template (including metafunction-id itself). See define-templatemetafunction for examples.

The ?? and ?@ forms and metafunction applications are disabled in an "escaped template" (see stat-template under syntax).

Example:

```
> (template (... ((?@ a b c) d)))
#<syntax:201:0 ((?@ a b c) d)>
??
?@
```

Auxiliary forms used by template. They may not be used as expressions.

```
(define-template-metafunction metafunction-id expr)
(define-template-metafunction (metafunction-id . formals) body ...+)
```

Defines metafunction-id as a template metafunction. A metafunction application in a template expression (but not a syntax expression) is evaluated by applying the metafunction to the result of processing the "argument" part of the template.

Examples:

```
> (define-template-metafunction (join stx)
    (syntax-parse stx
        [(join (~optional (~seq #:lctx lctx)) a:id b:id ...)
            (datum->syntax (or (attribute lctx) #'a)
                        (string->symbol
                            (apply string-append
                                    (map symbol->string
                                    (syntax->datum #'(a b ...)))))
                            stx)]))
> (template (join a b c))
#<syntax:203:0 abc>
> (with-syntax ([(x ...) #'(a b c)])
    (template ((x (join tmp- x)) ...)))
#<syntax:204:0 ((a tmp-a) (b tmp-b) (c tmp-c))>
```

Metafunctions are useful for performing transformations in contexts where macro expansion does not occur, such as binding occurrences. For example:

```
> (syntax->datum
    (with-syntax ([name #'posn]
                [(field ...) #'(x y)])
        (template (let-values ([((join name ?)
                            (join #:lctx name make- name)
                            (join name - field) ...)
                                (make-struct-type __)])
                                __))))
'(let-values (((posn? make-posn posn-x posn-y) (make-struct-type
__))) __)
```

If join were defined as a macro, it would not be usable in the context above; instead, letvalues would report an invalid binding list.

## 2 Syntax Object Helpers

### 2.1 Deconstructing Syntax Objects

```
(require syntax/stx) package: base
(stx-null? v) }->\mathrm{ boolean?
```

Returns \#t if $v$ is either the empty list or a syntax object representing the empty list (i.e., syntax-e on the syntax object returns the empty list).

## Examples:

```
> (stx-null? null)
#t
> (stx-null? #'())
#t
> (stx-null? #'(a))
#f
(stx-pair? v) }->\mathrm{ boolean?
```

Returns \#t if $v$ is either a pair or a syntax object representing a pair (see syntax pair).
Examples:

```
> (stx-pair? (cons #'a #'b))
#t
> (stx-pair? #'(a . b))
#t
> (stx-pair? #'())
#f
> (stx-pair? #'a)
#f
(stx-list? v) }->\mathrm{ boolean?
    v : any/c
```

Returns \#t if $v$ is a list, or if it is a sequence of pairs leading to a syntax object such that syntax->list would produce a list.

Examples:

```
    > (stx-list? #'(a b c d))
    #t
    > (stx-list? #'((a b) (c d)))
    #t
    > (stx-list? #'(a b (c d)))
    #t
    > (stx-list? (list #'a #'b))
    #t
    > (stx-list? #'a)
    #f
(stx->list stx-list) }->\mathrm{ (or/c list? #f)
    stx-list : stx-list?
```

Produces a list by flatting out a trailing syntax object using syntax->list.

## Examples:

```
> (stx->list #'(a b c d))
'(#<syntax:14:0 a> #<syntax:14:0 b> #<syntax:14:0 c> #<syntax:14:0
d>)
> (stx->list #'((a b) (c d)))
'(#<syntax:15:0 (a b)> #<syntax:15:0 (c d)>)
> (stx->list #'(a b (c d)))
'(#<syntax:16:0 a> #<syntax:16:0 b> #<syntax:16:0 (c d)>)
> (stx->list (list #'a #'b))
'(#<syntax:17:0 a> #<syntax:17:0 b>)
> (stx->list #'a)
#f
(stx-car v) }->\mathrm{ any
    v : stx-pair?
```

Takes the car of a syntax pair.
Examples:

```
> (stx-car #'(a b))
#<syntax:19:0 a>
> (stx-car (list #'a #'b))
#<syntax:20:0 a>
(stx-cdr v) }->\mathrm{ any
    v : stx-pair?
```

Takes the cdr of a syntax pair.

Examples:

```
> (stx-cdr #'(a b))
    '(#<syntax:21:0 b>)
> (stx-cdr (list #'a #'b))
    ,(#<syntax:22:0 b>)
(stx-map proc stxl ...) -> list?
    proc : procedure?
    stxl : stx-list?
```

Equivalent to (map proc (stx->list stxl) ...).
Example:

```
> (stx-map (\lambda (id) (free-identifier=? id #'a)) #'(a b c d))
,(#t #f #f #f)
(module-or-top-identifier=? a-id b-id) -> boolean?
    a-id : identifier?
    b-id : identifier?
```

Returns \#t if a-id and b-id are free-identifier=?, or if a-id and b-id have the same name (as extracted by syntax-e) and a-id has no binding other than at the top level.

This procedure is useful in conjunction with syntax-case* to match procedure names that are normally bound by Racket. For example, the include macro uses this procedure to recognize build-path; using free-identifier=? would not work well outside of module, since the top-level build-path is a distinct variable from the racket/base export (though it's bound to the same procedure, initially).

### 2.2 Matching Fully-Expanded Expressions

```
    (require syntax/kerncase) package: base
|(kernel-syntax-case stx-expr trans?-expr clause ...)
```

A syntactic form like syntax-case*, except that the literals are built-in as the names of the primitive Racket forms as exported by racket/base, including letrecsyntaxes+values; see §1.2.3.1 "Fully Expanded Programs".

The trans?-expr boolean expression replaces the comparison procedure, and instead selects simply between normal-phase comparisons or transformer-phase comparisons. The clause s are the same as in syntax-case*.

The primitive syntactic forms must have their normal bindings in the context of the kernel-syntax-case expression. Beware that kernel-syntax-case does not work in a module whose language is mzscheme, since the binding of if from mzscheme is different than the primitive if.

```
(kernel-syntax-case* stx-expr trans?-expr (extra-id ...) clause ...)
```

A syntactic form like kernel-syntax-case, except that it takes an additional list of extra literals that are in addition to the primitive Racket forms.

```
(kernel-syntax-case/phase stx-expr phase-expr clause ...)
```

Generalizes kernel-syntax-case to work at an arbitrary phase level, as indicated by phase-expr.

```
(kernel-syntax-case*/phase stx-expr phase-expr (extra-id ..)
    clause ...)
```

Generalizes kernel-syntax-case* to work at an arbitrary phase level, as indicated by phase-expr.
| (kernel-form-identifier-list) $\rightarrow$ (listof identifier?)

Returns a list of identifiers that are bound normally, for-syntax, and for-template to the primitive Racket forms for expressions, internal-definition positions, and module-level and top-level positions. This function is useful for generating a list of stopping points to provide to local-expand.

In addition to the identifiers listed in §1.2.3.1 "Fully Expanded Programs", the list includes letrec-syntaxes+values, which is the core form for local expand-time binding and can appear in the result of local-expand.

### 2.3 Dictionaries with Identifier Keys

```
(require syntax/id-table) package: base
```

This module provides two implementations of identifier tables: dictionaries with identifier keys that use identifier-specific comparisons instead of eq? or equal?. Identifier tables implement the racket/dict interface, and they are available in both mutable and immutable variants.

### 2.3.1 Dictionaries for free-identifier=?

A free-identifier table is a dictionary whose keys are compared using free-identifier=?. Free-identifier tables implement the dictionary interface of racket/dict, so all of the ap-
propriate generic functions (dict-ref, dict-map, etc) can be used on free-identifier tables.

```
(make-free-id-table [init-dict
                            #:phase phase]) }->\mathrm{ mutable-free-id-table?
    init-dict : dict? = null
    phase : (or/c exact-integer? #f) = (syntax-local-phase-level)
(make-immutable-free-id-table [init-dict
                                    #:phase phase])
-> immutable-free-id-table?
    init-dict : dict? = null
    phase : (or/c exact-integer? #f) = (syntax-local-phase-level)
```

Produces a mutable free-identifier table or immutable free-identifier table, respectively. The dictionary uses free-identifier=? to compare keys, but also uses a hash table based on symbol equality to make the dictionary efficient in the common case.

The identifiers are compared at phase level phase. The default phase, (syntax-local-phase-level), is generally appropriate for identifier tables used by macros, but code that analyzes fully-expanded programs may need to create separate identifier tables for each phase of the module.

The optional init-dict argument provides the initial mappings. It must be a dictionary, and its keys must all be identifiers. If the init-dict dictionary has multiple distinct entries whose keys are free-identifier=?, only one of the entries appears in the new id-table, and it is not specified which entry is picked.

```
(free-id-table? v) }->\mathrm{ boolean?
    v : any/c
```

Returns \#t if $v$ was produced by make-free-id-table or make-immutable-free-idtable, \#f otherwise.

```
(mutable-free-id-table? v) -> boolean?
```

Returns \#t if $v$ was produced by make-free-id-table, \#f otherwise.

```
(immutable-free-id-table? v) -> boolean?
    v : any/c
```

Returns \#t if $v$ was produced by make-immutable-free-id-table, \#f otherwise.

```
(free-id-table-ref table id [failure]) }->\mathrm{ any
    table : free-id-table?
    id : identifier?
    failure : any/c = (lambda () (raise (make-exn:fail .....)))
```

Like hash-ref. In particular, if id is not found, the failure argument is applied if it is a procedure, or simply returned otherwise.

```
(free-id-table-set! table id v) -> void?
    table : mutable-free-id-table?
    id : identifier?
    v : any/c
```

Like hash-set!.

```
(free-id-table-set table id v) -> immutable-free-id-table?
    table : immutable-free-id-table?
    id : identifier?
    v : any/c
```

Like hash-set.

```
(free-id-table-remove! table id) }->\mathrm{ void?
    table : mutable-free-id-table?
    id : identifier?
```

Like hash-remove!.

```
(free-id-table-remove table id) }->\mathrm{ immutable-free-id-table?
    table : immutable-free-id-table?
    id : identifier?
```

Like hash-remove.

```
(free-id-table-map table proc) -> list?
    table : free-id-table?
    proc : (-> identifier? any/c any)
```

Like hash-map.

```
(free-id-table-for-each table proc) -> void?
    table : free-id-table?
    proc : (-> identifier? any/c any)
```

Like hash-for-each.

```
(free-id-table-count table) }->\mathrm{ exact-nonnegative-integer?
    table : free-id-table?
```

Like hash-count.

```
(free-id-table-iterate-first table) -> id-table-iter?
    table : free-id-table?
(free-id-table-iterate-next table position) -> id-table-iter?
    table : free-id-table?
    position : id-table-iter?
(free-id-table-iterate-key table position) -> identifier?
    table : free-id-table?
    position : id-table-iter?
(free-id-table-iterate-value table
                                    position) -> identifier?
    table : bound-it-table?
    position : id-table-iter?
```

Like hash-iterate-first, hash-iterate-next, hash-iterate-key, and hash-iterate-value, respectively.

```
(id-table-iter? v) -> boolean?
    v : any/c
```

Returns \#t if $v$ represents a position in an identifier table (free or bound, mutable or immutable), \#f otherwise.

```
(free-id-table/c key-ctc
    val-ctc
    [#:immutable immutable?]) }->\mathrm{ contract?
    key-ctc : flat-contract?
    val-ctc : chaperone-contract?
    immutable?: (or/c #t #f 'dont-care) = 'dont-care
```

Like hash/c, but for free-identifier tables. If immutable? is \#t, the contract accepts only immutable identifier tables; if immutable? is \#f, the contract accepts only mutable identifier tables.

### 2.3.2 Dictionaries for bound-identifier=?

A bound-identifier table is a dictionary whose keys are compared using boundidentifier=? Bound-identifier tables implement the dictionary interface of racket/dict, so all of the appropriate generic functions (dict-ref, dict-map, etc) can be used on bound-identifier tables.

```
(make-bound-id-table [init-dict
    #:phase phase]) }->\mathrm{ mutable-bound-id-table?
    init-dict : dict? = null
    phase : (or/c exact-integer? #f) = (syntax-local-phase-level)
```

```
(make-immutable-bound-id-table [init-dict
                                    #:phase phase])
    -> immutable-bound-id-table?
    init-dict : dict? = null
    phase : (or/c exact-integer? #f) = (syntax-local-phase-level)
(bound-id-table? v) }->\mathrm{ boolean?
    v : any/c
(mutable-bound-id-table? v) -> boolean?
    v : any/c
(immutable-bound-id-table? v) }->\mathrm{ boolean?
    v : any/c
(bound-id-table-ref table id [failure]) }->\mathrm{ any
    table : bound-id-table?
    id : identifier?
    failure : any/c = (lambda () (raise (make-exn:fail .....)))
(bound-id-table-set! table id v) }->\mathrm{ void?
    table : mutable-bound-id-table?
    id : identifier?
    v : any/c
(bound-id-table-set table id v) -> immutable-bound-id-table?
    table : immutable-bound-id-table?
    id : identifier?
    v : any/c
(bound-id-table-remove! table id) }->\mathrm{ void?
    table : mutable-bound-id-table?
    id : identifier?
(bound-id-table-remove table id) }->\mathrm{ immutable-bound-id-table?
    table : immutable-bound-id-table?
    id : identifier?
(bound-id-table-map table proc) }->\mathrm{ list?
    table : bound-id-table?
    proc : (-> identifier? any/c any)
(bound-id-table-for-each table proc) }->\mathrm{ void?
    table : bound-id-table?
    proc : (-> identifier? any/c any)
(bound-id-table-count table) }->\mathrm{ exact-nonnegative-integer?
    table : bound-id-table?
(bound-id-table-iterate-first table) > id-table-position?
    table : bound-id-table?
(bound-id-table-iterate-next table
                        position) -> id-table-position?
    table : bound-id-table?
    position : id-table-position?
(bound-id-table-iterate-key table position) }->\mathrm{ identifier?
    table : bound-id-table?
    position : id-table-position?
```

```
(bound-id-table-iterate-value table
                                    position) -> identifier?
    table : bound-id-table?
    position : id-table-position?
(bound-id-table/c key-ctc
                        val-ctc
    [#:immutable immutable]) }->\mathrm{ contract?
key-ctc : flat-contract?
val-ctc : chaperone-contract?
immutable : (or/c #t #f 'dont-care) = 'dont-care
```

Like the procedures for free-identifier tables (make-free-id-table, free-id-tableref, etc), but for bound-identifier tables, which use bound-identifier=? to compare keys.

### 2.4 Hashing on bound-identifier=? and free-identifier=?

This library is for backwards-compatibility. Do not use it for new libraries; use syntax/idtable instead.

```
(require syntax/boundmap) package: base
(make-bound-identifier-mapping) -> bound-identifier-mapping?
(bound-identifier-mapping? v) }->\mathrm{ boolean?
    v : any/c
(bound-identifier-mapping-get bound-map
                                    id
                            [failure-thunk]) }->\mathrm{ any
    bound-map : bound-identifier-mapping?
    id : identifier?
    failure-thunk : (-> any)
                        = (lambda () (raise (make-exn:fail ....)))
(bound-identifier-mapping-put! bound-map
                                    id
                            v) }\quad\mathrm{ void?
    bound-map : bound-identifier-mapping?
    id : identifier?
    v : any/c
(bound-identifier-mapping-for-each bound-map
                            proc) }\quad->\mathrm{ void?
    bound-map : boud-identifier-mapping?
    proc : (identifier? any/c . -> . any)
(bound-identifier-mapping-map bound-map
                    proc) }->\mathrm{ (listof any?)
    bound-map : bound-identifier-mapping?
    proc : (identifier? any/c . -> . any)
```

Similar to make-bound-id-table, bound-id-table?, bound-id-table-ref, bound-id-table-set!, bound-id-table-for-each, and bound-id-table-map, respectively.

```
(make-free-identifier-mapping) }->\mathrm{ free-identifier-mapping?
(free-identifier-mapping? v) }->\mathrm{ boolean?
    v : any/c
(free-identifier-mapping-get free-map
                                    id
                                    [failure-thunk]) }->\mathrm{ any
    free-map : free-identifier-mapping?
    id : identifier?
    failure-thunk : (-> any)
                        = (lambda () (raise (make-exn:fail ....)))
(free-identifier-mapping-put! free-map id v) -> void?
    free-map : free-identifier-mapping?
    id : identifier?
    v : any/c
(free-identifier-mapping-for-each free-map
                                    proc) }\quad->\mathrm{ void?
    free-map : free-identifier-mapping?
    proc : (identifier? any/c . -> . any)
(free-identifier-mapping-map free-map proc) }->\mathrm{ (listof any?)
    free-map : free-identifier-mapping?
    proc : (identifier? any/c . -> . any)
```

Similar to make-free-id-table, free-id-table?, free-id-table-ref, free-id-table-set!, free-id-table-for-each, and free-id-table-map, respectively.

```
(make-module-identifier-mapping) }->\mathrm{ module-identifier-mapping?
(module-identifier-mapping? v) }->\mathrm{ boolean?
    v : any/c
(module-identifier-mapping-get module-map
                                    id
                                    [failure-thunk]) }->\mathrm{ any
    module-map : module-identifier-mapping?
    id : identifier?
    failure-thunk : (-> any)
    = (lambda () (raise (make-exn:fail ....)))
(module-identifier-mapping-put! module-map
                    id
                            v) }\quad->\mathrm{ void?
    module-map : module-identifier-mapping?
    id : identifier?
    v : any/c
```

```
(module-identifier-mapping-for-each module-map
                                    proc) }\quad->\mathrm{ void?
    module-map : module-identifier-mapping?
    proc : (identifier? any/c . -> . any)
(module-identifier-mapping-map module-map
                        proc) }\quad->\mathrm{ (listof any?)
    module-map : module-identifier-mapping?
    proc : (identifier? any/c . -> . any)
```

The same as make-free-identifier-mapping, etc.

### 2.5 Rendering Syntax Objects with Formatting

```
(require syntax/to-string) package: base
(syntax->string stx-list) }->\mathrm{ string?
    stx-list : stx-list?
```

Builds a string with newlines and indenting according to the source locations in stx-list; the outer pair of parens are not rendered from stx-list.

### 2.6 Computing the Free Variables of an Expression

```
(require syntax/free-vars) package: base
(free-vars expr-stx [insp]) }->\mathrm{ (listof identifier?)
    expr-stx : syntax?
    insp : inspector? = mod-decl-insp
```

Returns a list of free lambda- and let-bound identifiers in expr-stx in the order in which each identifier first appears within expr-stx. The expression must be fully expanded (see §1.2.3.1 "Fully Expanded Programs" and expand).

The inspector insp is used to disarm expr-stx and sub-expressions before extracting idenrifiers. The default insp is the declaration-time inspector of the syntax/free-vars module.

### 2.7 Replacing Lexical Context

(require syntax/strip-context) package: base

```
(strip-context stx) > syntax?
    stx : syntax?
```

Removes all lexical context from stx, preserving source-location information and properties.

```
(replace-context ctx-stx stx) }->\mathrm{ syntax?
    ctx-stx : (or/c syntax? #f)
    stx : syntax?
```

Uses the lexical context of ctx-stx to replace the lexical context of all parts of stx, preserving source-location information and properties of stx.

### 2.8 Helpers for Processing Keyword Syntax

The syntax/keyword module contains procedures for parsing keyword options in macros.

```
(require syntax/keyword) package: base
keyword-table = (dict-of keyword (listof check-procedure))
```

A keyword-table is a dictionary (dict?) mapping keywords to lists of check-procedures. (Note that an association list is a suitable dictionary.) The keyword's arity is the length of the list of procedures.

Example:

```
> (define my-keyword-table
    (list (list '#:a check-identifier)
            (list '#:b check-expression check-expression)))
check-procedure = (syntax syntax -> any)
```

A check procedure consumes the syntax to check and a context syntax object for error reporting and either raises an error to reject the syntax or returns a value as its parsed representation.

Example:

```
> (define (check-stx-string stx context-stx)
    (unless (string? (syntax-e stx))
        (raise-syntax-error #f "expected string" context-stx stx))
    stx)
```

```
options = (listof (list keyword syntax-keyword any ...))
```

Parsed options are represented as an list of option entries. Each entry contains the keyword, the syntax of the keyword (for error reporting), and the list of parsed values returned by the keyword's list of check procedures. The list contains the parsed options in the order they appeared in the input, and a keyword that occurs multiple times in the input occurs multiple times in the options list.

```
(parse-keyword-options stx
    table
    [#:context ctx
    #:no-duplicates? no-duplicates?
    #:incompatible incompatible
    #:on-incompatible incompatible-handler
    #:on-too-short too-short-handler
    #:on-not-in-table not-in-table-handler])
options any/c
    stx : syntax?
    table : keyword-table
    ctx : (or/c false/c syntax?) = #f
    no-duplicates? : boolean? = #f
    incompatible : (listof (listof keyword?)) = '()
    (-> keyword? keyword?
    incompatible-handler : options syntax? syntax?
                                    (values options syntax?))
            = (lambda (....) (error ....))
            (-> keyword? options syntax? syntax?
                (values options syntax?))
                        =(lambda (....) (error ....))
                        (-> keyword? options syntax? syntax?
                    (values options syntax?))
                        = (lambda (....) (error ....))
```

Parses the keyword options in the syntax stx (stx may be an improper syntax list). The keyword options are described in the table association list. Each entry in table should be a list whose first element is a keyword and whose subsequent elements are procedures for checking the arguments following the keyword. The keyword's arity (number of arguments) is determined by the number of procedures in the entry. Only fixed-arity keywords are supported.

Parsing stops normally when the syntax list does not have a keyword at its head (it may be empty, start with a non-keyword term, or it may be a non-list syntax object). Two values are returned: the parsed options and the rest of the syntax (generally either a syntax object or a list of syntax objects).

A variety of errors and exceptional conditions can occur during the parsing process. The
following keyword arguments determine the behavior in those situations.
The \#: context ctx argument is used to report all errors in parsing syntax. In addition, ctx is passed as the final argument to all provided handler procedures. Macros using parse-keyword-options should generally pass the syntax object for the whole macro use as $c t x$.

If no-duplicates? is a non-false value, then duplicate keyword options are not allowed. If a duplicate is seen, the keyword's associated check procedures are not called and an incompatibility is reported.

The incompatible argument is a list of incompatibility entries, where each entry is a list of at least two keywords. If any keyword in the entry occurs after any other keyword in the entry, an incompatibility is reported.

Note that including a keyword in an incompatibility entry does not prevent it from occurring multiple times. To disallow duplicates of some keywords (as opposed to all keywords), include those keywords in the incompatible list as being incompatible with themselves.
That is, include them twice:

```
; Disallow duplicates of only the #:foo keyword
(parse-keyword-options .... #:incompatible '((#:foo #:foo)))
```

When an incompatibility occurs, the incompatible-handler is tail-called with the two keywords causing the incompatibility (in the order that they occurred in the syntax list, so the keyword triggering the incompatibility occurs second), the syntax list starting with the occurrence of the second keyword, and the context (ctx). If the incompatibility is due to a duplicate, the two keywords are the same.

When a keyword is not followed by enough arguments according to its arity in table, the too-short-handler is tail-called with the keyword, the options parsed thus far, the syntax list starting with the occurrence of the keyword, and ctx.

When a keyword occurs in the syntax list that is not in table, the not-in-table-handler is tail-called with the keyword, the options parsed thus far, the syntax list starting with the occurrence of the keyword, and ctx.

Handlers typically escape-all of the default handlers raise errors-but if they return, they should return two values: the parsed options and a syntax object; these are returned as the results of parse-keyword-options.

## Examples:

```
> (parse-keyword-options
    #'(#:transparent #:property p (lambda (x) (f x)))
    (list (list '#:transparent)
            (list '#:inspector check-expression)
            (list '#:property check-expression check-expression)))
```

```
'((#:transparent #<syntax:4:0 #:transparent>)
    (#:property
    #<syntax:4:0 #:property>
    #<syntax:4:0 p>
    #<syntax:4:0 (lambda (x) (f x))>))
'()
> (parse-keyword-options
    #'(#:transparent #:inspector (make-inspector))
    (list (list '#:transparent)
            (list '#:inspector check-expression)
            (list '#:property check-expression check-expression))
    #:context #'define-struct
    #:incompatible '((#:transparent #:inspector)
                                    (#:inspector #:inspector)
                                    (#:inspector #:inspector)))
define-struct: #:inspector option not allowed after
#:transparent option
    (parse-keyword-options/eol
        stx
        table
    [#:context ctx
    #:no-duplicates? no-duplicates?
    #:incompatible incompatible
    #:on-incompatible incompatible-handler
    #:on-too-short too-short-handler
    #:on-not-in-table not-in-table-handler
    #:on-not-eol not-eol-handler])
options
    stx : syntax?
    table : keyword-table
    ctx : (or/c false/c syntax?) = #f
    no-duplicates? : boolean? = #f
    incompatible : (listof (list keyword? keyword?)) = '()
                            (-> keyword? keyword?
    incompatible-handler : options syntax? syntax?
                    (values options syntax?))
                        = (lambda (....) (error ....))
    too-short-handler : (-> keyword? options syntax? syntax?
                        (values options syntax?))
            = (lambda (....) (error ....))
    not-in-table-handler : (-> keyword? options syntax? syntax?
                                    (values options syntax?))
                            = (lambda (....) (error ....))
    not-eol-handler : (-> options syntax? syntax?
                options)
            = (lambda (....) (error ....))
```

Like parse-keyword-options, but checks that there are no terms left over after parsing all of the keyword options. If there are, not-eol-handler is tail-called with the options parsed thus far, the leftover syntax, and ctx.

```
(options-select options keyword) }->\mathrm{ (listof list?)
    options : options
    keyword : keyword?
```

Selects the values associated with one keyword from the parsed options. The resulting list has as many items as there were occurrences of the keyword, and each element is a list whose length is the arity of the keyword.

```
(options-select-row options
    keyword
    #:default default) -> any
    options : options
    keyword : keyword?
    default : any/c
```

Like options-select, except that the given keyword must occur either zero or one times in options. If the keyword occurs, the associated list of parsed argument values is returned. Otherwise, the default list is returned.

```
(options-select-value options
    keyword
    #:default default) -> any
    options : options
    keyword : keyword?
    default : any/c
```

Like options-select, except that the given keyword must occur either zero or one times in options. If the keyword occurs, the associated list of parsed argument values must have exactly one element, and that element is returned. If the keyword does not occur in options, the default value is returned.

```
(check-identifier stx ctx) }->\mathrm{ identifier?
    stx : syntax?
    ctx : (or/c false/c syntax?)
```

A check-procedure that accepts only identifiers.

```
(check-expression stx ctx) }->\mathrm{ syntax?
    stx : syntax?
    ctx : (or/c false/c syntax?)
```

A check-procedure that accepts any non-keyword term. It does not actually check that the term is a valid expression.

```
((check-stx-listof check) stx ctx) }->\mathrm{ (listof any/c)
    check : check-procedure
    stx : syntax?
    ctx : (or/c false/c syntax?)
```

Lifts a check-procedure to accept syntax lists of whatever the original procedure accepted.

```
(check-stx-string stx ctx) }->\mathrm{ syntax?
    stx : syntax?
    ctx : (or/c false/c syntax?)
```

A check-procedure that accepts syntax strings.

```
(check-stx-boolean stx ctx) }->\mathrm{ syntax?
    stx : syntax?
    ctx : (or/c false/c syntax?)
```

A check-procedure that accepts syntax booleans.

## 3 Datum Pattern Matching

```
(require syntax/datum) package: base
```

The syntax/datum library provides forms that implement the pattern and template language of syntax-case, but for matching and constructing datum values instead of syntax.

For most pattern-matching purposes, racket/match is a better choice than syntax/datum. The syntax/datum library is useful mainly for its template support (i.e., datum) and, to a lesser extent, its direct correspondence to syntax-case patterns.

```
(datum-case datum-expr (literal-id ...)
    clause ...)
(datum template)
```

Like syntax-case and syntax, but datum-expr in datum-case should produce a datum (i.e., plain S-expression) instead of a syntax object to be matched in clauses, and datum similarly produces a datum. Pattern variables bound in each clause of datum-case are accessible via datum instead of syntax. When a literal-id appears in a clause's pattern, it matches the corresponding symbol (using eq?).

Using datum-case and datum is essentially equivalent to converting the input to syntaxcase using datum->syntax and then wrapping each use of syntax with syntax->datum, but datum-case and datum to not create intermediate syntax objects.

Example:

```
> (datum-case '(1 "x" -> y) (->)
    [(a ... -> b) (datum (b (+ a) ...))])
    '(y (+ 1) (+ "x"))
(with-datum ([pattern datum-expr] ...)
    body ...+)
```

Analogous to with-syntax, but for datum-case and datum instead of syntax-case and syntax.

Example:

```
> (with-datum ([(a ...) '(1 2 3)]
            [(b ...) '("x" "y" "z")])
    (datum ((a b) ...)))
,((1 "x") (2 "y") (3 "z"))
(quasidatum template)
(undatum expr)
(undatum-splicing expr)
```

Analogous to quasisyntax, unsyntax, and unsyntax-splicing.
Example:
$>($ with-datum $([(\mathrm{a} . .$.$) \quad (1 2 \mathrm{3})])$
(quasidatum ((undatum (-1 1)) a ... (undatum (+ 2 2)))))
, ( $\left.\begin{array}{lllll}0 & 1 & 2 & 3 & 4\end{array}\right)$

## 4 Module-Processing Helpers

### 4.1 Reading Module Source Code

```
(require syntax/modread) package: base
(with-module-reading-parameterization thunk) }->\mathrm{ any
    thunk : (-> any)
```

Calls thunk with all reader parameters reset to their default values.

```
(check-module-form stx
    expected-module-sym
    source-v)
->(or/c syntax? false/c)
    stx : (or/c syntax? eof-object?)
    expected-module-sym : symbol?
    source-v : (or/c string? false/c)
```

Inspects stx to check whether evaluating it will declare a module-at least if module is bound in the top-level to Racket's module. The syntax object stx can contain a compiled expression. Also, stx can be an end-of-file, on the grounds that read-syntax can produce an end-of-file.

The expected-module-sym argument is currently ignored. In previous versions, the module form stx was obliged to declare a module who name matched expected-module-sym.

If stx can declare a module in an appropriate top-level, then the check-module-form procedure returns a syntax object that certainly will declare a module (adding explicit context to the leading module if necessary) in any top-level. Otherwise, if source-v is not \#f, a suitable exception is raised using the write form of the source in the message; if source-v is $\# f, \# f$ is returned.

If stx is eof or eof wrapped as a syntax object, then an error is raised or \#f is returned.

### 4.2 Getting Module Compiled Code

```
(require syntax/modcode) package: base
```

```
(get-module-code path
    [#:submodule-path submodule-path
    #:sub-path compiled-subdir0
    compiled-subdir
    #:roots roots
    #:compile compile-proc0
    compile-proc
    #:extension-handler ext-proc0
    ext-proc
    #:choose choose-proc
    #:notify notify-proc
    #:source-reader read-syntax-proc
    #:rkt-try-ss? rkt-try-ss?]) }\quad->\mathrm{ any
    path : path-string?
    submodule-path : (listof symbol?) = '()
    compiled-subdir0 : (and/c path-string? relative-path?)
            = "compiled"
    compiled-subdir : (and/c path-string? relative-path?)
            = compiled-subdir0
    roots : (listof (or/c path-string? 'same))
        = (current-compiled-file-roots)
    compile-proc0 : (any/c . -> . any) = compile
    compile-proc : (any/c . -> . any) = compile-proc0
    ext-proc0 : (or/c false/c (path? boolean? . -> . any)) = #f
    ext-proc : (or/c false/c (path? boolean? . -> . any))
            = ext-proc0
        (path? path? path?
    choose-proc : . -> .
        (or/c (symbols 'src 'zo 'so) false/c))
        = (lambda (src zo so) #f)
    notify-proc : (any/c . -> . any) = void
    read-syntax-proc : (any/c input-port? . -> . (or/c syntax? eof-object?))
            = read-syntax
    rkt-try-ss? : boolean? = #t
```

Returns a compiled expression for the declaration of the module specified by path and submodule-path, where submodule-path is empty for a root module or a list for a submodule.

The compiled-subdir argument defaults to "compiled"; it specifies the sub-directory to search for a compiled version of the module. The roots list specifies a compiled-file search path in the same way as the current-compiled-file-roots parameter.

The compile-proc argument defaults to compile. This procedure is used to compile module source if an already-compiled version is not available. If submodule-path is not '(), then compile-proc must return a compiled module form.

The ext-proc argument defaults to \#f. If it is not \#f, it must be a procedure of two arguments that is called when a native-code version of path should be used. In that case, the arguments to ext-proc are the path for the extension, and a boolean indicating whether the extension is a _loader file (\#t) or not (\#f).

The rkt-try-ss? argument defaults to \#t. If it is not \#f, then if path ends in ".rkt", then the corresponding file ending in ".ss" will be tried as well.

The choose-proc argument is a procedure that takes three paths: a source path, a ".zo" file path, and an extension path (for a non-_loader extension). Some of the paths may not exist. The result should be either 'src, 'zo, 'so, or \#f, indicating which variant should be used or (in the case of \#f) that the default choice should be used.

The default choice is computed as follows: if a ".zo" version of path is available and newer than path itself (in one of the directories specified by compiled-subdir), then it is used instead of the source. Native-code versions of path are ignored, unless only a nativecode non-_loader version exists (i.e., path itself does not exist). A _loader extension is selected a last resort.

If an extension is preferred or is the only file that exists, it is supplied to ext-proc when ext-proc is \#f, or an exception is raised (to report that an extension file cannot be used) when ext-proc is \#f.

If notify-proc is supplied, it is called for the file (source, ".zo" or extension) that is chosen.

If read-syntax-proc is provided, it is used to read the module from a source file (but not from a bytecode file).

```
(get-module-path path
    #:submodule? submodule?
    [#:sub-path compiled-subdir0
    compiled-subdir
    #:roots roots
    #:choose choose-proc
    #:rkt-try-ss? rkt-try-ss?])
-> path? (or/c 'src 'zo 'so)
    path : path-string?
    submodule? : boolean?
    compiled-subdir0 : (and/c path-string? relative-path?)
        = "compiled"
    compiled-subdir : (and/c path-string? relative-path?)
                            = compiled-subdir0
    roots : (listof (or/c path-string? 'same))
        = (current-compiled-file-roots)
```

```
    (path? path? path?
choose-proc : . ->
    (or/c (symbols 'src 'zo 'so) false/c))
    = (lambda (src zo so) #f)
rkt-try-ss? : boolean? = #t
```

Produces two values. The first is the path of the latest source or compiled file for the module specified by path; this result is the path of the file that get-module-code would read to produce a compiled module expression. The second value is 'src, 'zo, or 'so, depending on whether the first value represents a Racket source file, a compiled bytecode file, or a native library file.

The compiled-subdir, roots, choose-proc, and rkt-try-ss? arguments are interpreted the same as by get-module-code.

The submodule? argument represents whether the desired module is a submodule of the one specified by path. When submodule? is true, the result is never a 'so path, as native libraries cannot provide submodules.

```
(get-metadata-path path
    [#:roots roots]
    sub-path ...+) -> path?
    path : path-string?
    roots : (listof (or/c path? 'same))
        = (current-compiled-file-roots)
    sub-path : (or/c path-string? 'same)
```

Constructs the path used to store compilation metadata for a source file stored in the directory path. The argument roots specifies the possible root directories to consider and to search for an existing file. The sub-path arguments specify the subdirectories and filename of the result relative to the chosen root. For example, the compiled ".zo" file for "/path/to/source.rkt" might be stored in (get-metadata-path (build-path "/path/to") "compiled" "source_rkt.zo").

```
(moddep-current-open-input-file)
(path-string? . -> . input-port?)
(moddep-current-open-input-file proc) -> void?
    proc : (path-string? . -> . input-port?)
```

A parameter whose value is used like open-input-file to read a module source or ".zo" file.

```
(struct exn:get-module-code exn:fail (path)
    #:extra-constructor-name make-exn:get-module-code)
    path : path?
```

An exception structure type for exceptions raised by get-module-code.

### 4.3 Resolving Module Paths to File Paths

```
(require syntax/modresolve) package: base
(resolve-module-path module-path-v
    rel-to-path-v)
-> (or/c path? symbol?
(cons/c 'submod (cons/c (or/c path? symbol?) (listof symbol?))))
    module-path-v : module-path?
    rel-to-path-v : (or/c path-string? (-> any) false/c)
```

Resolves a module path to filename path. The module path is resolved relative to rel-to-path-v if it is a path string (assumed to be for a file), to the directory result of calling the thunk if it is a thunk, or to the current directory otherwise.

```
(resolve-module-path-index module-path-index
    rel-to-path-v)
(or/c path? symbol?
(cons/c 'submod (cons/c (or/c path? symbol?) (listof symbol?))))
    module-path-index : module-path-index?
    rel-to-path-v : (or/c path-string? (-> any) false/c)
```

Like resolve-module-path but the input is a module path index; in this case, the rel-to-path-v base is used where the module path index contains the "self" index. If module-path-index depends on the "self" module path index, then an exception is raised unless rel-to-path-v is a path string.

### 4.4 Simplifying Module Paths

```
(require syntax/modcollapse) package: base
(collapse-module-path module-path-v
            rel-to-module-path-v)
    -> (or/c path? module-path?)
    module-path-v : module-path?
    rel-to-module-path-v : (or/c module-path?
                                    (-> module-path?))
```

Returns a "simplified" module path by combining module-path-v with rel-to-module-path-v, where the latter must have one of the following forms: a' (lib ....) or symbol module path; a' (file ....) module path; a' (planet . . . .) module path; a path; ' (quote symbol); a' (submod base symbol ...) module path where base would be allowed; or a thunk to generate one of those.

The result can be a path if module-path-v contains a path element that is needed for the result, or if rel-to-module-path-v is a non-string path that is needed for the result. Similarly, the result can be 'submod wrapping a path. Otherwise, the result is a module path in the sense of module-path?

When the result is a 'lib or 'planet module path, it is normalized so that equivalent module paths are represented by equal? results. When the result is a 'submod module path, it contains only symbols after the base module path, and the base is normalized in the case of a'lib or 'planet base.

Examples:

```
> (collapse-module-path "m.rkt" ,(lib "n/main.rkt"))
,(lib "n/m.rkt")
> (collapse-module-path '(submod "." x) ,(lib "n/main.rkt"))
,(submod (lib "n/main.rkt") x)
> (collapse-module-path '(submod "." x) ,(submod (lib "n/main.rkt") y))
'(submod (lib "n/main.rkt") y x)
(collapse-module-path-index module-path-index
        rel-to-module-path-v)
-> (or/c path? module-path?)
    module-path-index : module-path-index?
    rel-to-module-path-v : (or/c module-path?
        (-> module-path?))
```

Like collapse-module-path, but the input is a module path index; in this case, the rel-to-module-path-v base is used where the module path index contains the "self" index.

### 4.5 Inspecting Modules and Module Dependencies

```
(require syntax/moddep) package: base
Re-exports syntax/modread, syntax/modcode, syntax/modcollapse, and syntax/modresolve, in addition to the following:
```

```
(show-import-tree module-path-v) -> void?
    module-path-v : module-path?
```

A debugging aid that prints the import hierarchy starting from a given module path.

## 5 Macro Transformer Helpers

### 5.1 Extracting Inferred Names

```
(require syntax/name) package: base
(syntax-local-infer-name stx) }->\mathrm{ any/c
    stx : syntax?
```

Similar to syntax-local-name except that stx is checked for an'inferred-name property (which overrides any inferred name). If neither syntax-local-name nor' inferredname produce a name, or if the 'inferred-name property value is \#<void>, then a name is constructed from the source-location information in stx, if any. If no name can be constructed, the result is \#f.

### 5.2 Support for local-expand

```
(require syntax/context) package: base
(build-expand-context v) }->\mathrm{ list?
    v : (or/c symbol? list?)
```

Returns a list suitable for use as a context argument to local-expand for an internaldefinition context. The $v$ argument represents the immediate context for expansion. The context list builds on (syntax-local-context) if it is a list.

```
| (generate-expand-context) -> list?
```

Calls build-expand-context with a generated symbol.

### 5.3 Parsing define-like Forms

```
(require syntax/define) package: base
(normalize-definition defn-stx
            lambda-id-stx
            [check-context?
                        opt+kws?]) }\quad->\mathrm{ identifier? syntax?
    defn-stx : syntax?
    lambda-id-stx : identifier?
    check-context? : boolean? = #t
    opt+kws? : boolean? = #f
```

Takes a definition form whose shape is like define (though possibly with a different name) and returns two values: the defined identifier and the right-hand side expression.

To generate the right-hand side, this function may need to insert uses of lambda. The lambda-id-stx argument provides a suitable lambda identifier.

If the definition is ill-formed, a syntax error is raised. If check-context? is true, then a syntax error is raised if (syntax-local-context) indicates that the current context is an expression context. The default value of check-context? is \#t.

If opt-kws? is \#t, then arguments of the form [id expr], keyword id, and keyword [id expr] are allowed, and they are preserved in the expansion.

### 5.4 Flattening begin Forms

```
(require syntax/flatten-begin) package: base
(flatten-begin stx) }->\mathrm{ (listof syntax?)
    stx : syntax?
```

Extracts the sub-expressions from a begin-like form, reporting an error if stx does not have the right shape (i.e., a syntax list). The resulting syntax objects have annotations transferred from stx using syntax-track-origin.

### 5.5 Expanding define-struct-like Forms

(require syntax/struct) package: base

```
(parse-define-struct stx orig-stx) : }\begin{array}{rl}{}&{\mathrm{ identifier? }}\\{\mathrm{ (or/c identifier? false/c)}}\\{\mathrm{ (listof identifier?)}}\\{\mathrm{ syntax? }}
    stx : syntax?
    orig-stx : syntax?
```

Parses stx as a define-struct form, but uses orig-stx to report syntax errors (under the assumption that orig-stx is the same as stx, or that they at least share sub-forms). The result is four values: an identifier for the struct type name, a identifier or \#f for the super-name, a list of identifiers for fields, and a syntax object for the inspector expression.

```
(build-struct-names name-id
                        field-ids
    [#:constructor-name ctr-name]
    omit-sel?
    omit-set?
    [src-stx])
(listof identifier?)
    name-id : identifier?
    field-ids : (listof identifier?)
    ctr-name : (or/c identifier? #f) = #f
    omit-sel?: boolean?
    omit-set? : boolean?
    src-stx : (or/c syntax? false/c) = #f
```

Generates the names bound by define-struct given an identifier for the struct type name and a list of identifiers for the field names. The result is a list of identifiers:

- struct: name-id
- ctr-name, or make-name-id if ctr-name is \#f
- name-id?
- name-id-field, for each field in field-ids.
- set-name-id-field! (getter and setter names alternate).
- ....

If omit-sel? is true, then the selector names are omitted from the result list. If omit-set? is true, then the setter names are omitted from the result list.

The default src-stx is \#f; it is used to provide a source location to the generated identifiers.

```
(build-struct-generation name-id
    field-ids
    [#:constructor-name ctr-name]
    omit-sel?
    omit-set?
    [super-type
    prop-value-list
    immutable-k-list])
-> (listof identifier?)
    name-id : identifier?
    field-ids : (listof identifier?)
    ctr-name : (or/c identifier? #f) = #f
    omit-sel?: boolean?
```

```
omit-set? : boolean?
super-type : any/c = #f
prop-value-list : list? = '(list)
immutable-k-list : list? = '(list)
```

Takes the same arguments as build-struct-names and generates an S-expression for code using make-struct-type to generate the structure type and return values for the identifiers created by build-struct-names. The optional super-type, prop-value-list, and immutable-k-list parameters take S-expressions that are used as the corresponding argument expressions to make-struct-type.

```
(build-struct-generation* all-name-ids
    name-id
    field-ids
    [#:constructor-name ctr-name]
    omit-sel?
    omit-set?
    [super-type
    prop-value-list
    immutable-k-list])
-> (listof identifier?)
    all-name-ids : (listof identifier?)
    name-id : identifier?
    field-ids : (listof identifier?)
    ctr-name : (or/c identifier? #f) = #f
    omit-sel? : boolean?
    omit-set? : boolean?
    super-type : any/c = #f
    prop-value-list : list? = '(list)
    immutable-k-list : list? = '(list)
```

Like build-struct-generation, but given the names produced by build-structnames, instead of re-generating them.

```
(build-struct-expand-info name-id
    field-ids
    [#:omit-constructor? no-ctr?
    #:constructor-name ctr-name
    #:omit-struct-type? no-type?]
    omit-sel?
    omit-set?
    base-name
    base-getters
    base-setters) }\quad->\mathrm{ any
name-id : identifier?
```

```
field-ids : (listof identifier?)
no-ctr? : any/c = #f
ctr-name : (or/c identifier? #f) = #f
no-type? : any/c = #f
omit-sel? : boolean?
omit-set? : boolean?
base-name : (or/c identifier? boolean?)
base-getters : (listof (or/c identifier? false/c))
base-setters : (listof (or/c identifier? false/c))
```

Takes mostly the same arguments as build-struct-names, plus a parent identifier/\#t/\#f and a list of accessor and mutator identifiers (possibly ending in $\# f$ ) for a parent type, and generates an S-expression for expansion-time code to be used in the binding for the structure name.

If no-ctr? is true, then the constructor name is omitted from the expansion-time information. Similarly, if no-type? is true, then the structure-type name is omitted.

A \#t for the base-name means no super-type, \#f means that the super-type (if any) is unknown, and an identifier indicates the super-type identifier.

```
(struct-declaration-info? v) -> boolean?
    v : any/c
```

Returns \#t if x has the shape of expansion-time information for structure type declarations, \#f otherwise. See $\S 5.7$ "Structure Type Transformer Binding".

```
(generate-struct-declaration orig-stx
    name-id
    super-id-or-false
    field-id-list
    current-context
    make-make-struct-type
    [omit-sel?
    omit-set?]) }\quad->\mathrm{ syntax?
    orig-stx : syntax?
    name-id : identifier?
    super-id-or-false : (or/c identifier? false/c)
    field-id-list : (listof identifier?)
    current-context : any/c
    make-make-struct-type : procedure?
    omit-sel? : boolean? = #f
    omit-set? : boolean? = #f
```

This procedure implements the core of a define-struct expansion.

The generate-struct-declaration procedure is called by a macro expander to generate the expansion, where the name-id, super-id-or-false, and field-id-list arguments provide the main parameters. The current-context argument is normally the result of syntax-local-context. The orig-stx argument is used for syntax errors. The optional omit-sel? and omit-set? arguments default to \#f; a \#t value suppresses definitions of field selectors or mutators, respectively.

The make-struct-type procedure is called to generate the expression to actually create the struct type. Its arguments are orig-stx, name-id-stx, defined-name-stxes, and super-info. The first two are as provided originally to generate-struct-declaration, the third is the set of names generated by build-struct-names, and the last is super-struct info obtained by resolving super-id-or-false when it is not $\# f, \# f$ otherwise.

The result should be an expression whose values are the same as the result of make-structtype. Thus, the following is a basic make-make-struct-type:

```
(lambda (orig-stx name-stx defined-name-stxes super-info)
    #'(make-struct-type '#,name-stx
    #,(and super-info (list-ref super-info 0))
    #,(/ (- (length defined-name-stxes) 3) 2)
    0 #f))
```

but an actual make-make-struct-type will likely do more.

### 5.6 Resolving include-like Paths

```
(require syntax/path-spec) package: base
(resolve-path-spec path-spec-stx
                source-stx
                expr-stx
                build-path-stx) -> complete-path?
    path-spec-stx : syntax?
    source-stx : syntax?
    expr-stx : syntax?
    build-path-stx : syntax?
```

Resolves the syntactic path specification path-spec-stx as for include.
The source-stx specifies a syntax object whose source-location information determines relative-path resolution. The expr-stx is used for reporting syntax errors. The build-path-stx is usually \#'build-path; it provides an identifier to compare to parts of path-spec-stx to recognize the build-path keyword.

### 5.7 Controlling Syntax Templates

```
(require syntax/template) package: base
(transform-template template-stx
    #:save save-proc
    #:restore-stx restore-proc-stx
    [#:leaf-save leaf-save-proc
    #:leaf-restore-stx leaf-restore-proc-stx
    #:leaf-datum-stx leaf-datum-proc-stx
    #:pvar-save pvar-save-proc
    #:pvar-restore-stx pvar-restore-stx
    #:cons-stx cons-proc-stx
    #:ellipses-end-stx ellipses-end-stx
    #:constant-as-leaf? constant-as-leaf?])
syntax?
    template-stx : syntax?
    save-proc : (syntax? . -> . any/c)
    restore-proc-stx : syntax?
    leaf-save-proc : (syntax? . -> . any/c) = save-proc
    leaf-restore-proc-stx : syntax? = #'(lambda (data stx) stx)
    leaf-datum-proc-stx : syntax? = #'(lambda (v) v)
    pvar-save-proc : (identifier? . -> . any/c) = (lambda (x) #f)
    pvar-restore-stx : syntax? = #'(lambda (d stx) stx)
    cons-proc-stx : syntax? = cons
    ellipses-end-stx : syntax? = #'values
    constant-as-leaf? : boolean? = #f
```

Produces an representation of an expression similar to \#‘(syntax \#, template-stx), but functions like save-proc can collect information that might otherwise be lost by syntax (such as properties when the syntax object is marshaled within bytecode), and run-time functions like the one specified by restore-proc-stx can use the saved information or otherwise process the syntax object that is generated by the template.

The save-proc is applied to each syntax object in the representation of the original template (i.e., in template-stx). If constant-as-leaf? is \#t, then save-proc is applied only to syntax objects that contain at least one pattern variable in a sub-form. The result of save-proc is provided back as the first argument to restore-proc-stx, which indicates a function with a contract (-> any/c syntax any/c any/c); the second argument to restore-proc-stx is the syntax object that syntax generates, and the last argument is a datum that have been processed recursively (by functions such as restore-proc-stx) and that normally would be converted back to a syntax object using the second argument's context, source, and properties. Note that save-proc works at expansion time (with respect to the template form), while restore-proc-stx indicates a function that is called at run time (for the template form), and the data that flows from save-proc to restore-procstx crosses phases via quote.

The leaf-save-proc and leaf-restore-proc-stx procedures are analogous to saveproc and restore-proc-stx, but they are applied to leaves, so there is no third argument for recursively processed sub-forms. The function indicated by leaf-restore-proc-stx should have the contract ( $->$ any/c syntax? any/c).

The leaf-datum-proc-stx procedure is applied to leaves that are not syntax objects, which can happen because pairs and the empty list are not always individually wrapped as syntax objects. The function should have the contract ( $->$ any/c any/c). When constant-as-leaf? is \#f, the only possible argument to the procedure is null.

The pvar-save and pvar-restore-stx procedures are analogous to save-proc and restore-proc-stx, but they are applied to pattern variables. The pvar-restore-stx procedure should have the contract ( $->$ any/c syntax? any/c), where the second argument corresponds to the substitution of the pattern variable.

The cons-proc-stx procedure is used to build intermediate pairs, including pairs passed to restore-proc-stx and pairs that do not correspond to syntax objects.

The ellipses-end-stx procedure is an extra filter on the syntax object that follows a sequence of . . . ellipses in the template. The procedure should have the contract ( $->$ any/c any/c).

The following example illustrates a use of transform-template to implement a syntax/shape form that preserves the 'paren-shape property from the original template, even if the template code is marshaled within bytecode.

```
(define-for-syntax (get-shape-prop stx)
    (syntax-property stx 'paren-shape))
(define (add-shape-prop v stx datum)
    (syntax-property (datum->syntax stx datum stx stx stx)
                            'paren-shape
                            v))
(define-syntax (syntax/shape stx)
    (syntax-case stx ()
        [(_ tmpl)
            (transform-template #'tmpl
                                    #:save get-shape-prop
                                    #:restore-stx #'add-shape-prop)]))
```

## 6 Reader Helpers

### 6.1 Raising exn:fail:read

```
(require syntax/readerr) package: base
(raise-read-error msg-string
        source
        line
        col
        pos
        span
    [#:extra-srclocs extra-srclocs]) }->\mathrm{ any
    msg-string : string?
    source : any/c
    line : (or/c number? false/c)
    col : (or/c number? false/c)
    pos : (or/c number? false/c)
    span : (or/c number? false/c)
    extra-srclocs : (listof srcloc?) = '()
```

Creates and raises an exn:fail:read exception, using msg-string as the base error message.

Source-location information is added to the error message using the last five arguments and the extra-srclocs (if the error-print-source-location parameter is set to \#t). The source argument is an arbitrary value naming the source location-usually a file path string. Each of the line, pos arguments is \#f or a positive exact integer representing the location within source-name (as much as known), col is a non-negative exact integer for the source column (if known), and span is $\# f$ or a non-negative exact integer for an item range starting from the indicated position.

The usual location values should point at the beginning of whatever it is you were reading, and the span usually goes to the point the error was discovered.

```
(raise-read-eof-error msg-string
    source
    line
    col
    pos
    span) }\quad->\mathrm{ any
    msg-string : string?
    source : any/c
    line : (or/c number? false/c)
    col : (or/c number? false/c)
```

```
pos : (or/c number? false/c)
span : (or/c number? false/c)
```

Like raise-read-error, but raises exn:fail:read:eof instead of exn:fail:read.

### 6.2 Module Reader

See also §17.3
"Defining new \#lang Languages" in The Racket Guide.

The syntax/module-reader library provides support for defining \#lang readers. It is normally used as a module language, though it may also be required to get make-metareader. It provides all of the bindings of racket/base other than \#\%module-begin.

```
(#%module-begin module-path)
(#%module-begin module-path reader-option ... form ....)
(#%module-begin reader-option ... form ....)
reader-option = #:read read-expr
    | #:read-syntax read-syntax-expr
    | #:whole-body-readers? whole?-expr
    | #:wrapper1 wrapper1-expr
    | #:wrapper2 wrapper2-expr
    | #:language lang-expr
    | #:info info-expr
    | #:language-info language-info-expr
    read-expr : (input-port? . -> . any/c)
    read-syntax-expr : (any/c input-port? . -> . any/c)
    whole-expr : any/c
    wrapper1-expr : \begin{array}{rlc}{(or/c ((-> any/c) . -> . any/c) }\end{array}((->\mathrm{ any/c) boolean? . -> . any/c))}
        (or/c (input-port? (input-port? . -> . any/c)
    wrapper2-expr : . -> . any/c)
        (input-port? (input-port? . -> . any/c)
        boolean? . -> . any/c))
    info-expr : (symbol? any/c (symbol? any/c . -> . any/c) . -> . any/c)
    module-info-expr : (or/c (vector/c module-path? symbol? any/c) #f)
    (or/c module-path?
    lang-expr : (and/c syntax? (compose module-path? syntax->datum))
                        procedure?)
```

In its simplest form, the body of a module written with syntax/module-reader contains
just a module path, which is used in the language position of read modules. For example, a module something/lang/reader implemented as

```
    (module reader syntax/module-reader
    module-path)
```

creates a reader such that a module source

```
#lang something
```

....
is read as

```
(module name-id module-path
    (#%module-begin ....))
```

where name-id is derived from the source input port's name in the same way as for \#lang s-exp.

Keyword-based reader-options allow further customization, as listed below. Additional forms are as in the body of racket/base module; they can import bindings and define identifiers used by the reader-options.

- \#:read and \#:read-syntax (both or neither must be supplied) specify alternate readers for parsing the module body-replacements read and read-syntax, respectively. Normally, the replacements for read and read-syntax are applied repeatedly to the module source until eof is produced, but see also \#:whole-body-readers?.
Unless \#: whole-body-readers? specifies a true value, the repeated use of read or read-syntax is parameterized to set read-accept-lang to $\# f$, which disables nested uses of \#lang.
See also \#:wrapper1 and \#:wrapper2, which support simple parameterization of readers rather than wholesale replacement.
- \#:whole-body-readers? specified as true indicates that the \#:read and \#:readsynt ax functions each produce a list of S-expressions or syntax objects for the module content, so that each is applied just once to the input stream.
If the resulting list contains a single form that starts with the symbol ' \#\% modulebegin (or a syntax object whose datum is that symbol), then the first item is used as the module body; otherwise, a '\#\%module-begin (symbol or identifier) is added to the beginning of the list to form the module body.
- \#:wrapper1 specifies a function that controls the dynamic context in which the read and read-syntax functions are called. A \#:wrapper1-specified function must accept a thunk, and it normally calls the thunk to produce a result while parameterizing the call. Optionally, a \#: wrapper1-specified function can accept a boolean that indicates whether it is used in read (\#f) or read-syntax (\#t) mode.

For example, a language like racket/base but with case-insensitive reading of symbols and identifiers can be implemented as

```
(module reader syntax/module-reader
    racket/base
    #:wrapper1 (lambda (t)
                                    (parameterize ([read-case-sensitive #f])
                                    (t))))
```

Using a readtable, you can implement languages that are extensions of plain Sexpressions.

- \#:wrapper2 is like \#:wrapper1, but a \#:wrapper2-specified function receives the input port to be read, and the function that it receives accepts an input port (usually, but not necessarily the same input port). A \# : wrapper2-specified function can optionally accept an boolean that indicates whether it is used in read (\#f) or read-syntax (\#t) mode.
- \#:info specifies an implementation of reflective information that is used by external tools to manipulate the source of modules in the language something. For example, DrRacket uses information from \#: info to determine the style of syntax coloring that it should use for editing a module's source.

The \#: info specification should be a function of three arguments: a symbol indicating the kind of information requested (as defined by external tools), a default value that normally should be returned if the symbol is not recognized, and a default-filtering function that takes the first two arguments and returns a result.
The expression after \#:info is placed into a context where language-module and language-data are bound. The language-module identifier is bound to the module-path that is used for the read module's language as written directly or as determined through \#: language. The language-data identifier is bound to the second result from \#: language, or \#f by default.
The default-filtering function passed to the \#:info function is intended to provide support for information that syntax/module-reader can provide automatically. Currently, it recognizes only the 'module-language key, for which it returns language-module; it returns the given default value for any other key.
In the case of the DrRacket syntax-coloring example, DrRacket supplies 'colorlexer as the symbol argument, and it supplies \#f as the default. The default-filtering argument (i.e., the third argument to the \#:info function) currently just returns the default for 'color-lexer.

- \#:language-info specifies an implementation of reflective information that is used by external tools to manipulate the module in the language something in its expanded, compiled, or declared form (as opposed to source). For example, when Racket starts a program, it uses information attached to the main module to initialize the run-time environment.

Submodules are normally a better way to implement reflective information, instead of \#:language-info. For example, when Racket starts a program, it also checks for a configure-runtime submodule of the main module to initialize the run-time environment. The \#: language-info mechanism pre-dates submodules.
Since the expanded/compiled/declared form exists at a different time than when the source is read, a \#:language-info specification is a vector that indicates an implementation of the reflective information, instead of a direct implementation as a function like \#: info. The first element of the vector is a module path, the second is a symbol corresponding to a function exported from the module, and the last element is a value to be passed to the function. The last value in the vector must be one that can be written with write and read back with read. When the exported function indicated by the first two vector elements is called with the value from the last vector element, the result should be a function or two arguments: a symbol and a default value. The symbol and default value are used as for the \#:info function (but without an extra default-filtering function).
The value specified by \#:language-info is attached to the module form that is parsed from source through the 'module-language syntax property. See module for more information.
The expression after \#:language-info is placed into a context where languagemodule are language-data are bound, the same as for \#:info.
In the case of the Racket run-time configuration example, Racket uses the \#:language-info vector to obtain a function, and then it passes 'configureruntime to the function to obtain information about configuring the runtime environment. See also §18.1.5 "Language Run-Time Configuration".

- \#:language allows the language of the read module to be computed dynamically and based on the program source, instead of using a constant module-path. (Either \#: language or module-path must be provided, but not both.)
This value of the \#: language option can be either a module path (possibly as a syntax object) that is used as a module language, or it can be a procedure. If it is a procedure it can accept either
- 0 arguments;
- 1 argument: an input port; or
- 5 arguments: an input port, a syntax object whose datum is a module path for the enclosing module as it was referenced through \#lang or \#reader, a starting line number (positive exact integer) or \#f, a column number (non-negative exact integer) or $\# f$, and a position number (positive exact integer) or $\# f$.

The result can be either

- a single value, which is a module path or a syntax object whose datum is a module path, to be used like module-path; or
- two values, where the first is like a single-value result and the second can be any value.

The second result, which defaults to \#f if only a single result is produced, is made available to the \#:info and \#:module-info functions through the language-data binding. For example, it can be a specification derived from the input stream that changes the module's reflective information (such as the syntax-coloring mode or the output-printing styles).

As another example, the following reader defines a "language" that ignores the contents of the file, and simply reads files as if they were empty:

```
(module ignored syntax/module-reader
    racket/base
    #:wrapper1 (lambda (t) (t) '()))
```

Note that the wrapper still performs the read, otherwise the module loader would complain about extra expressions.

As a more useful example, the following module language is similar to at-exp, where the first datum in the file determines the actual language (which means that the library specification is effectively ignored):

```
(module reader syntax/module-reader
    -ignored-
    \#:wrapper2
    (lambda (in rd stx?)
        (let* ([lang (read in)]
                        [mod (parameterize ([current-readtable
                                    (make-at-readtable)])
                                    (rd in))]
                [mod (if stx? mod (datum->syntax \#f mod))]
                [r (syntax-case mod ()
                            [(module name lang* . body)
                            (with-syntax ([lang (datum->syntax
                                    \#'lang* lang \#'lang*)])
                                    (syntax/loc mod (module name lang . body)))])])
            (if stx? r (syntax->datum r))))
    (require scribble/reader))
```

The ability to change the language position in the resulting module expression can be useful in cases such as the above, where the base language module is chosen based on the input. To make this more convenient, you can omit the module-path and instead specify it via a \#:language expression. This expression can evaluate to a datum or syntax object that is used as a language, or it can evaluate to a thunk. In the latter case, the thunk is invoked to obtain such a datum before reading the module body begins, in a dynamic extent where current-input-port is the source input. A syntax object is converted using syntax>datum when a datum is needed (for read instead of read-syntax). Using \#:language, the last example above can be written more concisely:

```
(module reader syntax/module-reader
    #:language read
    #:wrapper2 (lambda (in rd stx?)
                            (parameterize ([current-readtable
                                    (make-at-readtable)])
                                (rd in)))
    (require scribble/reader))
```

For such cases, however, the alternative reader constructor make-meta-reader implements a might tightly controlled reading of the module language.

```
(make-meta-reader self-sym
    path-desc-str
    [#:read-spec read-spec]
    module-path-parser
    convert-read
    convert-read-syntax
    convert-get-info)
-> procedure? procedure? procedure?
    self-sym : symbol?
    path-desc-str : string?
    read-spec : (input-port? . -> . any/c) = (lambda (in) ....)
    module-path-parser : (any/c . -> . (or/c module-path? #f
                            (vectorof module-path?)))
    convert-read : (procedure? . -> . procedure?)
    convert-read-syntax : (procedure? . -> . procedure?)
    convert-get-info : (procedure? . -> . procedure?)
```

Generates procedures suitable for export as read (see read and \#lang), read-syntax (see read-syntax and \#lang), and get-info (see read-language and \#lang), respectively, where the procedures chains to another language that is specified in an input stream.

The generated functions expect a target language description in the input stream that is provided to read-spec. The default read-spec extracts a non-empty sequence of bytes after one or more space and tab bytes, stopping at the first whitespace byte or end-of-file (whichever is first), and it produces either such a byte string or \#f. If read-spec produces $\# f$, a reader exception is raised, and path-desc-str is used as a description of the expected language form in the error message.

The result of read-spec is converted to a module path using module-path-parser. If module-path-parser produces a vector of module paths, they are tried in order using module-declared?. If module-path-parser produces \#f, a reader exception is raised in the same way as when read-spec produces a \#f. The planet languages supply a module-path-parser that converts a byte string to a module path.

The at-exp,
reader, and
planet languages are implemented using this function.

## The reader

 language supplies read for read-spec. The at-exp and planet languages use the default read-spec.If loading the module produced by module-path-parser succeeds, then the loaded mod-
ule's read, read-syntax, or get-info export is passed to convert-read, convert-read-syntax, or convert-get-info, respectively.

The procedures generated by make-meta-reader are not meant for use with the syntax/module-reader language; they are meant to be exported directly.

```
(wrap-read-all mod-path
    in
    read
    mod-path-stx
    src
    line
    col
    pos) }\quad->\mathrm{ any/c
mod-path : module-path?
in : input-port?
read : (input-port . -> . any/c)
mod-path-stx : syntax?
src : (or/c syntax? #f)
line : number?
col : number?
pos : number?
```

This function is deprecated; the syntax/module-reader language can be adapted using the various keywords to arbitrary readers; please use it instead.

Repeatedly calls read on in until an end of file, collecting the results in order into lst, and derives a name-id from (object-name in) in the same way as \#lang s-exp. The last five arguments are used to construct the syntax object for the language position of the module. The result is roughly

```
'(module ,name-id ,mod-path ,@lst)
```

## 7 Parsing for Bodies

```
(require syntax/for-body) package: base
```

The syntax/for-body module provides a helper function for $f$ or-like syntactic forms that wrap the body of the form while expanding to another for-like form, and the wrapper should apply only after the last \#: break or \#:final clause in the body.

```
(split-for-body stx body-stxes) }->\mathrm{ syntax?
    stx : syntax?
    body-stxes : syntax?
```

The body-stxes argument must have the form (pre-body ... post-body ...), and it is rewritten into ((pre-body ...) (post-body ...)) such that (post-body ...) is as large as possible without containing a \#:break or \#:final clause.

The stx argument is used only for reporting syntax errors.
Use split-for-body instead of assuming that the last form in a for-like form's body can be wrapped separately. In particular, the last form might contain definitions that need to be spliced in the same definition context as earlier forms to create mutually-recursive definitions.

## 8 Unsafe for Clause Transforms

```
(require syntax/unsafe/for-transform) package: base
```

The syntax/unsafe/for-transform module provides a helper function that gives access to the sequence transformers defined by define-sequence-syntax. This is what the for forms use and enables faster sequence traversal than what the sequence interface provides.

The output may use unsafe operations.

```
(expand-for-clause orig-stx clause) -> syntax?
    orig-stx : syntax?
    clause : syntax?
```

Expands a for clause of the form [(x . . .) seq-expr], where x are identifiers, to:

```
(([(outer-id ...) outer-expr] ...)
    outer-check
    ([loop-id loop-expr] ...)
    pos-guard
    ([(inner-id ...) inner-expr] ...)
    pre-guard
    post-guard
    (loop-arg ...))
```

which can then be spliced into the appropriate iterations. See : do-in for more information.
The result may use unsafe operations.
The first argument orig-stx is used only for reporting syntax errors.

## 9 Source Locations

There are two libraries in this collection for dealing with source locations; one for manipulating representations of them, and the other for quoting the location of a particular piece of source code.

### 9.1 Representations

```
(require syntax/srcloc) package: base
```

This module defines utilities for manipulating representations of source locations, including both srcloc structures and all the values accepted by datum->syntax's third argument: syntax objects, lists, vectors, and \#f.

```
(source-location? x) \(\rightarrow\) boolean?
    \(x\) : any/c
(source-location-list? x) \(\rightarrow\) boolean?
    x : any/c
(source-location-vector? x) \(\rightarrow\) boolean?
    \(x\) : any/c
```

These functions recognize valid source location representations. The first, sourcelocation?, recognizes srcloc structures, syntax objects, lists, and vectors with appropriate structure, as well as \#f. The latter predicates recognize only valid lists and vectors, respectively.

## Examples:

```
> (source-location? #f)
#t
> (source-location? #'here)
#t
>(source-location? (make-srcloc 'here 1 0 1 0))
#t
>(source-location? (make-srcloc 'bad 1 #f 1 0))
#f
> (source-location? (list 'here 1 0 1 0))
#t
> (source-location? (list* 'bad 1 0 1 0 'tail))
#f
> (source-location? (vector 'here 1 0 1 0))
#t
> (source-location? (vector 'bad 0 0 0 0))
#f
```

```
(check-source-location! name x) }->\mathrm{ void?
    name : symbol?
    x : any/c
```

This procedure checks that its input is a valid source location. If it is, the procedure returns (void). If it is not, check-source-location! raises a detailed error message in terms of name and the problem with $x$.

Examples:

```
> (check-source-location! 'this-example #f)
> (check-source-location! 'this-example #'here)
> (check-source-location! 'this-example (make-
srcloc 'here 1 0 1 0))
> (check-source-location! 'this-example (make-
srcloc 'bad 1 #f 1 0))
this-example: expected a source location with line number
and column number both numeric or both #f; got 1 and #f
respectively: (srcloc 'bad 1 #f 1 0)
> (check-source-location! 'this-example (list 'here 1 0 1 0))
> (check-source-location! 'this-example (list* 'bad 1 0 1 0 'tail))
this-example: expected a source location (a list of 5
elements); got an improper list: '(bad 1 0 1 0. tail)
> (check-source-location! 'this-example (vector 'here 1 0 1 0))
> (check-source-location! 'this-example (vector 'bad 0 0 0 0))
this-example: expected a source location with a positive
line number or #f (second element); got line number 0:
    '#(bad 0 0 0 0)
(build-source-location loc ...) -> srcloc?
    loc : source-location?
(build-source-location-list loc ...) }->\mathrm{ source-location-list?
    loc : source-location?
(build-source-location-vector loc ...) -> source-location-vector?
    loc : source-location?
(build-source-location-syntax loc ...) -> syntax?
    loc : source-location?
```

These procedures combine multiple (zero or more) source locations, merging locations within the same source and reporting \#f for locations that span sources. They also convert the result to the desired representation: srcloc, list, vector, or syntax object, respectively.

Examples:

```
> (build-source-location)
(srcloc #f #f #f #f #f)
> (build-source-location-list)
'(#f #f #f #f #f)
> (build-source-location-vector)
'#(#f #f #f #f #f)
> (build-source-location-syntax)
#<syntax ()>
> (build-source-location #f)
(srcloc #f #f #f #f #f)
> (build-source-location-list #f)
'(#f #f #f #f #f)
> (build-source-location-vector #f)
'#(#f #f #f #f #f)
> (build-source-location-syntax #f)
#<syntax ()>
> (build-source-location (list 'here 1 2 3 4))
(srcloc 'here 1 2 3 4)
> (build-source-location-list (make-srcloc 'here 1 2 3 4))
,(here 1 2 3 4)
> (build-source-location-vector (make-srcloc 'here 1 2 3 4))
'#(here 1 2 3 4)
> (build-source-location-syntax (make-srcloc 'here 1 2 3 4))
#<syntax:1:2 ()>
> (build-source-location (list 'here 1 2 3 4) (vector 'here 5 6 7 8))
(srcloc 'here 1 2 3 12)
> (build-source-location-list (make-srcloc 'here 1 2 3 4) (vector 'here 5 6 7 8))
,(here 1 2 3 12)
> (build-source-location-vector (make-srcloc 'here 1 2 3 4) (vector 'here 5 6 7 8))
'#(here 1 2 3 12)
> (build-source-location-syntax (make-srcloc 'here 1 2 3 4) (vector 'here 5 6 7 8))
#<syntax:1:2 ()>
> (build-source-location (list 'here 1 2 3 4) (vector 'there 5 6 7 8))
(srcloc #f #f #f #f #f)
> (build-source-location-list (make-srcloc 'here 1 2 3 4) (vector 'there 5 6 7 8))
'(#f #f #f #f #f)
> (build-source-location-vector (make-srcloc 'here 1 2 3 4) (vector 'there 5 6 7 8))
'#(#f #f #f #f #f)
> (build-source-location-syntax (make-srcloc 'here 1 2 3 4) (vector 'there 5 6 7 8))
#<syntax ()>
(source-location-known? loc) }->\mathrm{ boolean?
    loc : source-location?
```

This predicate reports whether a given source location contains more information than sim-
ply \#f.
Examples:

```
> (source-location-known? #f)
#f
> (source-location-known? (make-srcloc #f #f #f #f #f))
#f
>(source-location-known? (make-srcloc 'source 1 2 3 4))
#t
> (source-location-known? (list #f #f #f #f #f))
#f
> (source-location-known? (vector 'source #f #f #f #f))
#t
> (source-location-known? (datum->syntax #f null #f))
#f
> (source-location-known? (datum->syntax #f null (list 'source #f #f #f #f)))
#t
(source-location-source loc) }->\mathrm{ any/c
    loc : source-location?
(source-location-line loc)
    (or/c orexact-positive-integer? #f)
    loc : source-location?
(source-location-column loc)
(or/c exact-nonnegative-integer? #f)
    loc : source-location?
(source-location-position loc)
    -> (or/c exact-positive-integer? #f)
    loc : source-location?
(source-location-span loc)
(or/c exact-nonnegative-integer? #f)
    loc : source-location?
```

These accessors extract the fields of a source location.

## Examples:

```
> (source-location-source #f)
#f
>(source-location-line (make-srcloc 'source 1 2 3 4))
1
>(source-location-column (list 'source 1 2 3 4))
2
(source-location-position (vector 'source 1 2 3 4))
3
> (source-location-span (datum->syntax #f null (list 'source 1 2 3 4)))
4
```

```
(source-location-end loc)
(or/c exact-nonnegative-integer? #f)
    loc : source-location?
```

This accessor produces the end position of a source location (the sum of its position and span, if both are numbers) or \#f.

Examples:

```
> (source-location-end #f)
#f
> (source-location-end (make-srcloc 'source 1 2 3 4))
7
>(source-location-end (list 'source 1 2 3 #f))
#f
> (source-location-end (vector 'source 1 2 #f 4))
#f
(update-source-location loc
    #:source source
    #:line line
    #:column column
    #:position position
    #:span span) }->\mathrm{ source-location?
loc : source-location?
source : any/c
line : (or/c exact-nonnegative-integer? #f)
column : (or/c exact-positive-integer? #f)
position : (or/c exact-nonnegative-integer? #f)
span : (or/c exact-positive-integer? #f)
```

Produces a modified version of loc, replacing its fields with source, line, column, position, and/or span, if given.

Examples:

```
> (update-source-location #f #:source 'here)
'(here #f #f #f #f)
> (update-source-location (list 'there 1 2 3 4) #:line 20 #:column 79)
'(there 20 79 3 4)
> (update-source-location (vector 'everywhere 1 2 3 4) #:position #f #:span #f)
'#(everywhere 1 2 #f #f)
(source-location->string loc) -> string?
    loc : source-location?
(source-location->prefix loc) -> string?
    loc : source-location?
```

These procedures convert source locations to strings for use in error messages. The first produces a string describing the source location; the second appends ": " to the string if it is non-empty.

Examples:

```
> (source-location->string (make-srcloc 'here 1 2 3 4))
"here:1.2"
> (source-location->string (make-srcloc 'here #f #f 3 4))
"here::3-7"
> (source-location->string (make-srcloc 'here #f #f #f #f))
"here"
> (source-location->string (make-srcloc #f 1 2 3 4))
":1.2"
> (source-location->string (make-srcloc #f #f #f 3 4))
": :3-7"
> (source-location->string (make-srcloc #f #f #f #f #f))
""
> (source-location->prefix (make-srcloc 'here 1 2 3 4))
"here:1.2: "
> (source-location->prefix (make-srcloc 'here #f #f 3 4))
"here::3-7: "
> (source-location->prefix (make-srcloc 'here #f #f #f #f))
"here: "
> (source-location->prefix (make-srcloc #f 1 2 3 4))
":1.2: "
> (source-location->prefix (make-srcloc #f #f #f 3 4))
"::3-7: "
> (source-location->prefix (make-srcloc #f #f #f #f #f))
""
```

### 9.2 Quoting

```
(require syntax/location) package: base
```

This module defines macros that evaluate to various aspects of their own source location.
Note: The examples below illustrate the use of these macros and the representation of their output. However, due to the mechanism by which they are generated, each example is considered a single character and thus does not have realistic line, column, and character positions.

Furthermore, the examples illustrate the use of source location quoting inside macros, and the difference between quoting the source location of the macro definition itself and quoting the source location of the macro's arguments.

```
(quote-srcloc)
(quote-srcloc form)
(quote-srcloc form #:module-source expr)
```

Quotes the source location of form as a srcloc structure, using the location of the whole (quote-srcloc) expression if no expr is given. Uses relative directories for paths found within the collections tree, the user's collections directory, or the PLaneT cache.

Examples:

```
> (quote-srcloc)
    (srcloc 'eval 2 0 2 1)
> (define-syntax (not-here stx) #'(quote-srcloc))
> (not-here)
(srcloc 'eval 3 0 3 1)
> (not-here)
(srcloc 'eval 3 0 3 1)
> (define-syntax (here stx) #'(quote-srcloc #,stx))
> (here)
(srcloc 'eval 7 0 7 1)
> (here)
(srcloc 'eval 8 0 8 1)
(quote-source-file)
(quote-source-file form)
(quote-line-number)
(quote-line-number form)
(quote-column-number)
(quote-column-number form)
(quote-character-position)
(quote-character-position form)
(quote-character-span)
(quote-character-span form)
```

Quote various fields of the source location of form, or of the whole macro application if no form is given.

Examples:

```
> (list (quote-source-file)
    (quote-line-number)
    (quote-column-number)
    (quote-character-position)
    (quote-character-span))
,(eval 2 0 2 1)
```

```
> (define-syntax (not-here stx)
    #'(list (quote-source-file)
                                    (quote-line-number)
                                    (quote-column-number)
                                    (quote-character-position)
            (quote-character-span)))
> (not-here)
    ,(eval 3 0 3 1)
> (not-here)
    ,(eval 3 0 3 1)
> (define-syntax (here stx)
        #'(list (quote-source-file #,stx)
                            (quote-line-number #,stx)
                    (quote-column-number #,stx)
                    (quote-character-position #,stx)
                    (quote-character-span #,stx)))
> (here)
    ,(eval 7 0 7 1)
> (here)
    '(eval 8 0 8 1)
(quote-srcloc-string)
(quote-srcloc-string form)
(quote-srcloc-prefix)
(quote-srcloc-prefix form)
```

Quote the result of source-location->string or source-location->prefix, respectively, applied to the source location of form, or of the whole macro application if no form is given.

Examples:

```
> (list (quote-srcloc-string)
    (quote-srcloc-prefix))
,("eval:2.0" "eval:2.0: ")
> (define-syntax (not-here stx)
    #'(list (quote-srcloc-string)
            (quote-srcloc-prefix)))
> (not-here)
,("eval:3.0" "eval:3.0: ")
> (not-here)
,("eval:3.0" "eval:3.0: ")
> (define-syntax (here stx)
```

```
    #'(list (quote-srcloc-string #,stx)
            (quote-srcloc-prefix #,stx)))
> (here)
    ,("eval:7.0" "eval:7.0: ")
> (here)
    '("eval:8.0" "eval:8.0: ")
|(quote-module-name submod-path-element ...)
```

Quotes the name of the module in a form suitable for printing, but not necessarily as a valid module path. See quote-module-path for constructing quoted module paths.

Returns a path, symbol, list, or 'top-level, where 'top-level is produced when used outside of a module. A list corresponds to a submodule in the same format as the result of variable-reference->module-name. Any given submod-path-elements (as in a submod form) are added to form a result submodule path.

To produce a name suitable for use in printed messages, apply path->relativestring/library when the result is a path.

## Examples:

```
> (module A racket
    (require syntax/location)
    (define-syntax-rule (name) (quote-module-name))
    (define a-name (name))
    (module+ C
        (require syntax/location)
        (define c-name (quote-module-name))
        (define c-name2 (quote-module-name ".."))
        (provide c-name c-name2))
        (provide (all-defined-out)))
> (require 'A)
> a-name
,A
> (require (submod 'A C))
> c-name
'(A C)
> c-name2
,(A C "..")
> (module B racket
    (require syntax/location)
    (require 'A)
```

```
    (define b-name (name))
    (provide (all-defined-out)))
> (require 'B)
> b-name
'B
> (quote-module-name)
'top-level
> (current-namespace (module->namespace ,'A))
> (quote-module-name)
,A
|(quote-module-path submod-path-element ...)
```

Quotes the name of the module in which the form is compiled. When possible, the result is a valid module path suitable for use by dynamic-require and similar functions.

Builds the result using quote, a path, submod, or 'top-level, where 'top-level is produced when used outside of a module. Any given submod-path-elements (as in a submod form) are added to form a result submodule path.

## Examples:

```
> (module A racket
    (require syntax/location)
    (define-syntax-rule (path) (quote-module-path))
    (define a-path (path))
    (module+ C
        (require syntax/location)
        (define c-path (quote-module-path))
        (define c-path2 (quote-module-path ".."))
        (provide c-path c-path2))
        (provide (all-defined-out)))
> (require 'A)
> a-path
,'A
> (require (submod 'A C))
> c-path
'(submod 'A C)
> c-path2
'(submod 'A C "..")
```

```
> (module B racket
        (require syntax/location)
        (require 'A)
        (define b-path (path))
        (provide (all-defined-out)))
> (require 'B)
> b-path
, ,B
> (quote-module-path)
'top-level
> (current-namespace (module->namespace ,'A))
> (quote-module-path)
,'A
```

## 10 Preserving Source Locations

```
(require syntax/quote) package: base
```

The syntax/quote module provides support for quoting syntax so that it's source locations are preserved in marshaled bytecode form.

```
(quote-syntax/keep-srcloc datum)
(quote-syntax/keep-srcloc #:source source-expr datum)
```

Like (quote-syntax datum), but the source locations of datum are preserved. If a source-expr is provided, then it is used in place of a syntax-source value for each syntax object within datum.

Unlike a quote-syntax form, the results of evaluating the expression multiple times are not necessarily eq?.

## 11 Non-Module Compilation And Expansion

```
(require syntax/toplevel) package: base
(expand-syntax-top-level-with-compile-time-evals stx) -> syntax?
    stx : syntax?
```

Expands stx as a top-level expression, and evaluates its compile-time portion for the benefit of later expansions.

The expander recognizes top-level begin expressions, and interleaves the evaluation and expansion of of the begin body, so that compile-time expressions within the begin body affect later expansions within the body. (In other words, it ensures that expanding a begin is the same as expanding separate top-level expressions.)

The stx should have a context already, possibly introduced with namespace-syntaxintroduce.

```
(expand-top-level-with-compile-time-evals stx) -> syntax?
    stx : syntax?
```

Like expand-syntax-top-level-with-compile-time-evals, but stx is first given context by applying namespace-syntax-introduce to it.

```
(expand-syntax-top-level-with-compile-time-evals/flatten stx)
    (listof syntax?)
    stx : syntax?
```

Like expand-syntax-top-level-with-compile-time-evals, except that it returns a list of syntax objects, none of which have a begin. These syntax objects are the flattened out contents of any begins in the expansion of stx.

```
(eval-compile-time-part-of-top-level stx) -> void?
    stx : syntax?
```

Evaluates expansion-time code in the fully expanded top-level expression represented by stx (or a part of it, in the case of begin expressions). The expansion-time code might affect the compilation of later top-level expressions. For example, if stx is a require expression, then namespace-require/expansion-time is used on each require specification in the form. Normally, this function is used only by expand-top-level-with-compile-timeevals.

```
(eval-compile-time-part-of-top-level/compile stx)
    -> (listof compiled-expression?)
    stx : syntax?
```

Like eval-compile-time-part-of-top-level, but the result is compiled code.

## 12 Trusting Standard Recertifying Transformers

```
(require syntax/trusted-xforms) package: base
```

The syntax/trusted-xforms library has no exports. It exists only to require other modules that perform syntax transformations, where the other transformations must use syntaxdisarm or syntax-arm. An application that wishes to provide a less powerful code inspector to a sub-program should generally attach syntax/trusted-xforms to the subprogram's namespace so that things like the class system from racket/class work properly.

## 13 Attaching Documentation to Exports

```
(require syntax/docprovide) package: base
(provide-and-document doc-label-id doc-row ...)
doc-row = (section-string (name type-datum doc-string ...) ...)
    | (all-from prefix-id module-path doc-label-id)
    | (all-from-except prefix-id module-path doc-label-id id ...)
    name = id
    | (local-name-id external-name-id)
```

A form that exports names and records documentation information.
The doc-label-id identifier is used as a key for accessing the documentation through lookup-documentation. The actual documentation is organized into "rows", each with a section title.

A row has one of the following forms:

- (section-string (name type-datum doc-string ...) ...)

Creates a documentation section whose title is section-string, and provides/documents each name. The type-datum is arbitrary, for use by clients that call lookup-documentation. The doc-strings are also arbitrary documentation information, usually concatenated by clients.

A name is either an identifier or a renaming sequence (local-name-id extenal-name-id).
Multiple rows with the same section name will be merged in the documentation output. The final order of sections matches the order of the first mention of each section.

- (all-from prefix-id module-path doc-label-id)
- (all-from-except prefix-id module-path doc-label-id id ...)

Merges documentation and provisions from the specified module into the current one; the prefix-id is used to prefix the imports into the current module (so they can be re-exported). If ids are provided, the specified ids are not re-exported and their documentation is not merged.

```
(lookup-documentation module-path-v
    label-sym) }->\mathrm{ any
    module-path-v : module-path?
    label-sym : symbol?
```

Returns documentation for the specified module and label. The module-path-v argument is a quoted module path, like the argument to dynamic-require. The label-sym identifies a set of documentation using the symbol as a label identifier in provide-and-document.
